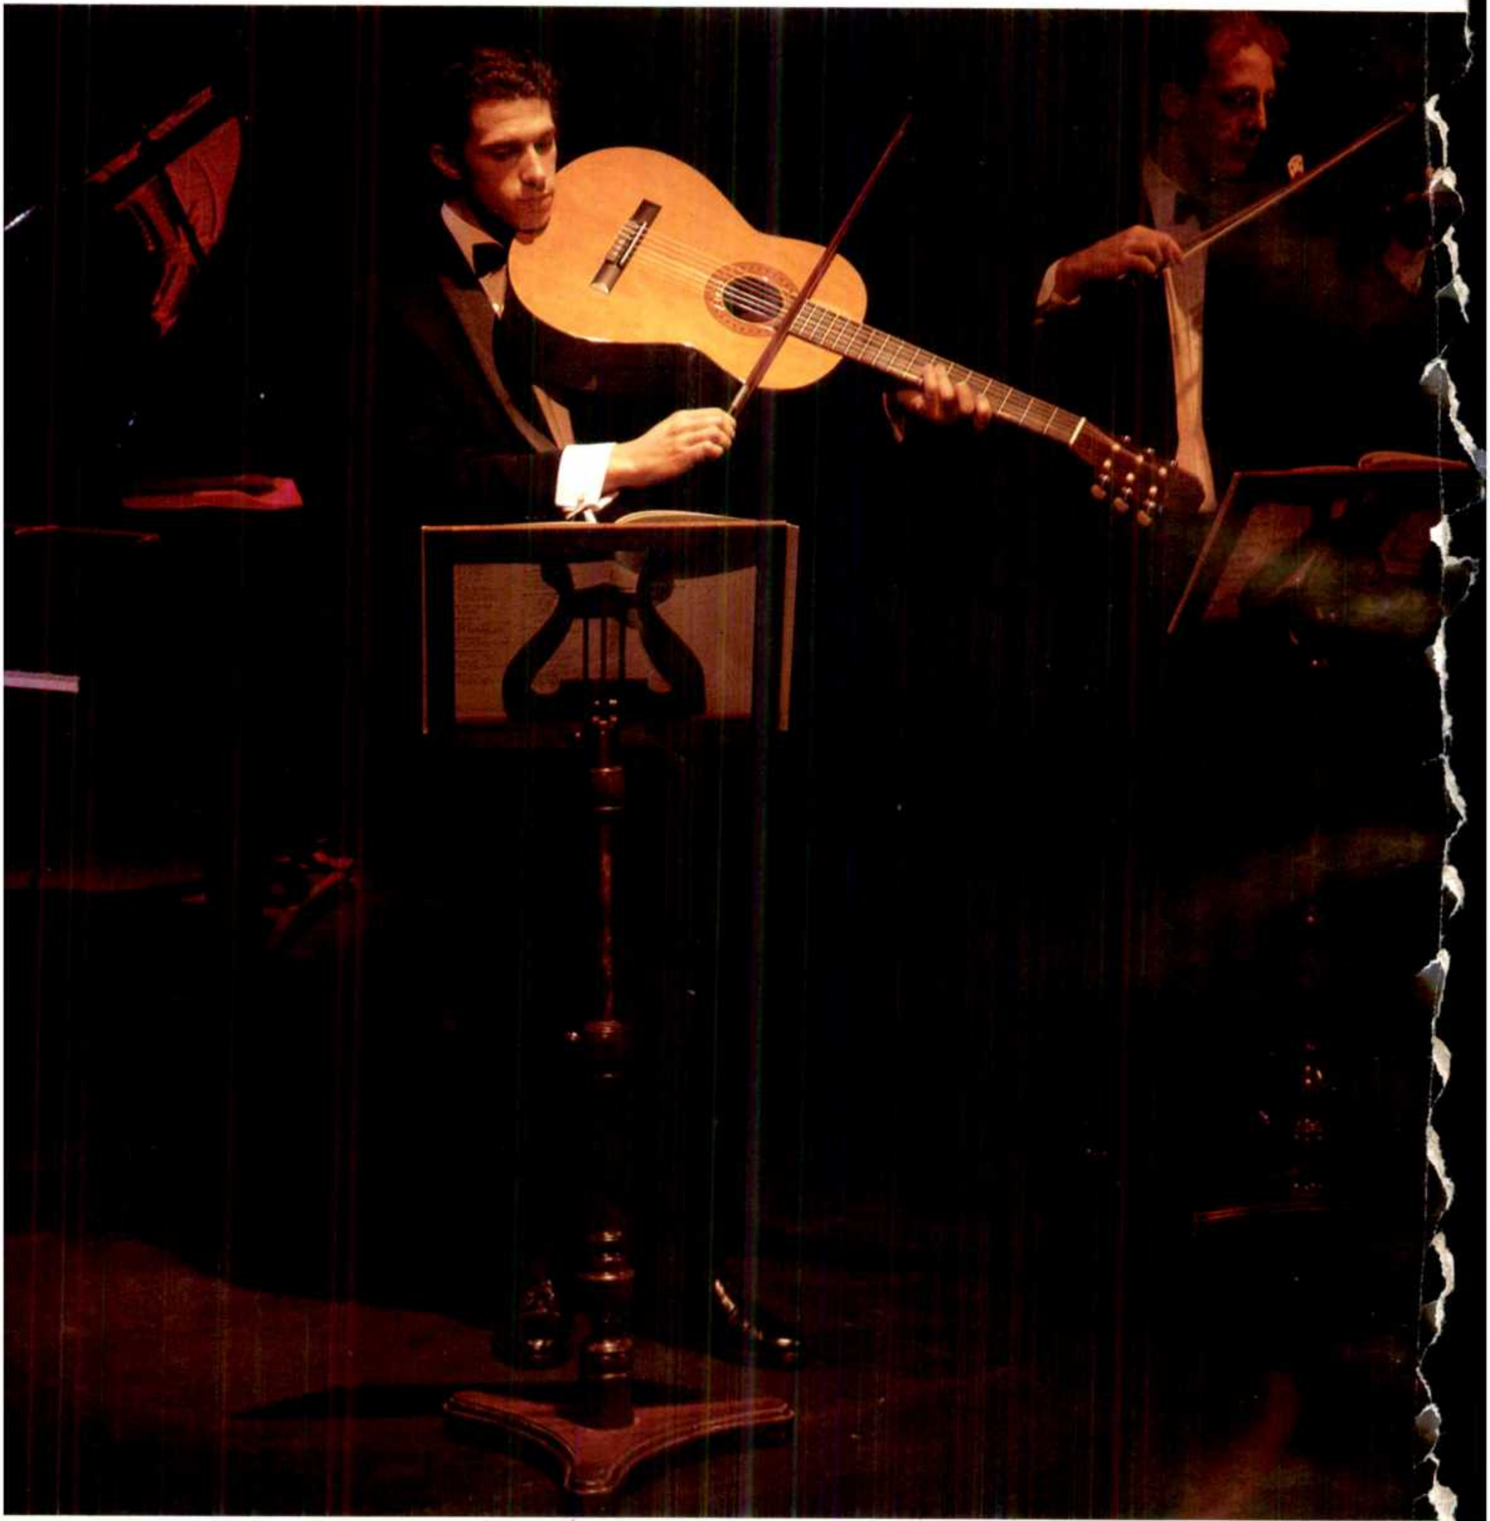
TO ACHIEVE THE PERFECT PERFORMANC
USE THE RIGHT INSTRUMENTS.



Keeping in tune with today's minimal invasive surgical procedures makes it more essential than ever to have the right backing in the instrument section.

Because when it comes to the precision of *ELECTROSURGICAL* equipment, you need to know you can rely on the performance. And you certainly won't want any sudden shocks during your own solo performance.

So it's good to hear that with Eschmann products, you can tune up on years of experience in surgical practices and *ELECTROSURGICAL* technology. And we certainly don't play second fiddle when it comes to safety, reliability and performance.

We can even orchestrate our product range to suit the specialist concerned, including a choice of bipolar and monopolar generators, a wide range of output modes and an impressive list of accessories.

And since all Eschmann products are backed by the highest quality standards, full service back-up and a unique range of safety features... our name is likely to be music to your ears.

ESCHMANN
EQUIPMEN

YOU'RE NOT PROPERLY EQUIPPED WITHOUT US.

Eschmann Equipment Division, Peter Road, Lancing, West Sussex BN15 8TJ, England. Telephone (0903) 753322. Telex: 877075. Fax (0903) 766793.

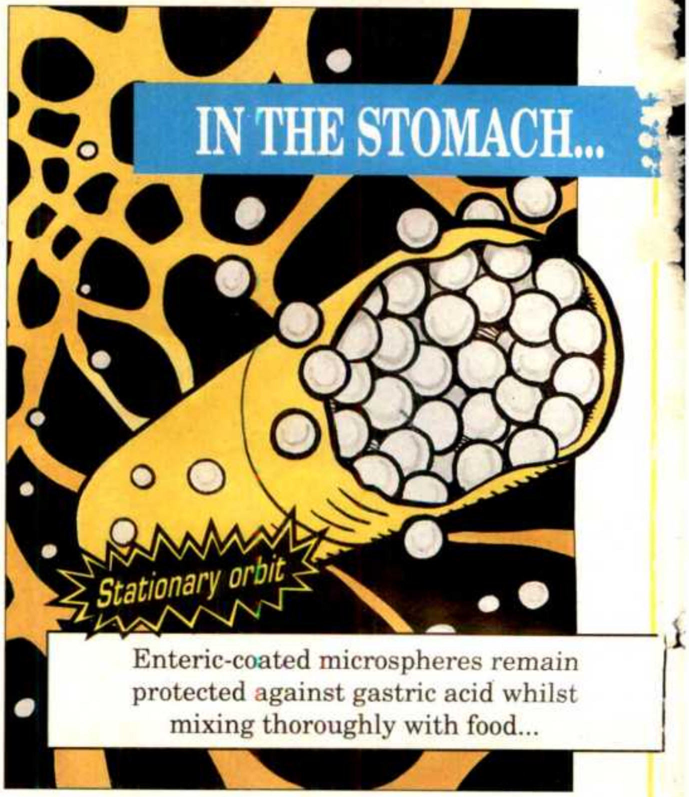
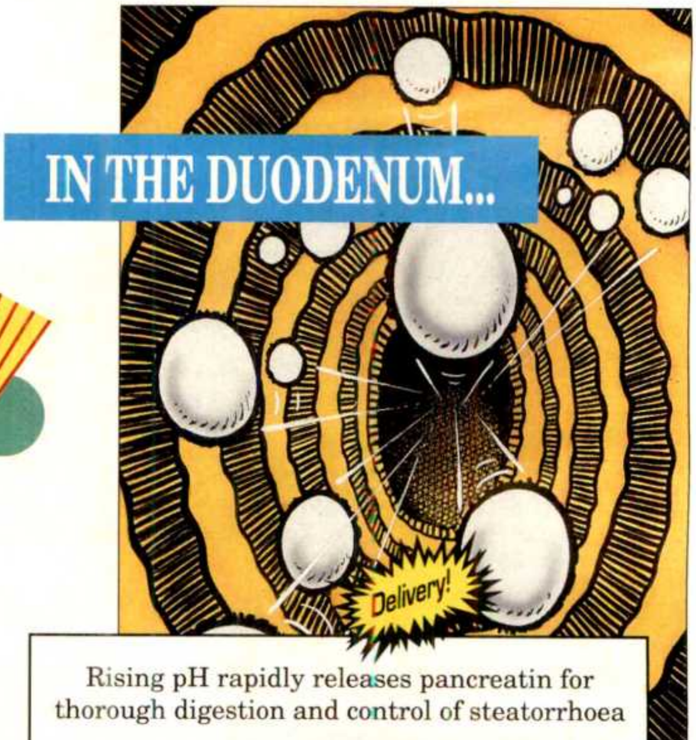
A REAL FORCE IN PANCREATIC EXOCRINE INSUFFICIENCY



IN THE STOMACH...
Stationary orbit
Enteric-coated microspheres remain protected against gastric acid whilst mixing thoroughly with food...



IN THE DUODENUM...
Delivery!
Rising pH rapidly releases pancreatin for thorough digestion and control of steatorrhoea

creon®
pancreatin 25000

Superior control of steatorrhoea†

† Compared with standard enteric-coated tablets in pancreatic insufficiency[1,2]

Prescribing Information

Presentation: Opaque orange/yellow hard gelatin capsules containing brownish coloured enteric coated pellets of pancreatin, equivalent to:

25,000 PhEur. units of lipase
18,000 PhEur. units of amylase
1,000 PhEur. units of protease (total)

Available in packs of 50. Basic NHS price £19.50.

Indication: Pancreatic exocrine insufficiency.

Dosage and Administration: Adults (including elderly) and children: Initially one capsule with meals, then adjust according to response. The capsules can be swallowed whole, or for ease of administration they may be opened and the granules taken with fluid or soft food, but without chewing. If the granules are mixed with food it is important that they are taken immediately, otherwise dissolution of the enteric coating may result.

Contra-indications, Warnings, etc. Contra-indications: Substitution with pancreatic enzymes is contra-indicated in the early stages of acute pancreatitis. Warnings: Use in pregnancy: There is inadequate evidence of safety in use during pregnancy. The product is of porcine origin. Rarely cases of hyper-uricosuria and hyper-uricaemia have been reported with very high doses of pancreatin. Overdosage although not experienced until now, could precipitate meconium ileus equivalen Ferianal irritation, and rarely, inflammation, could occur when large doses are used.

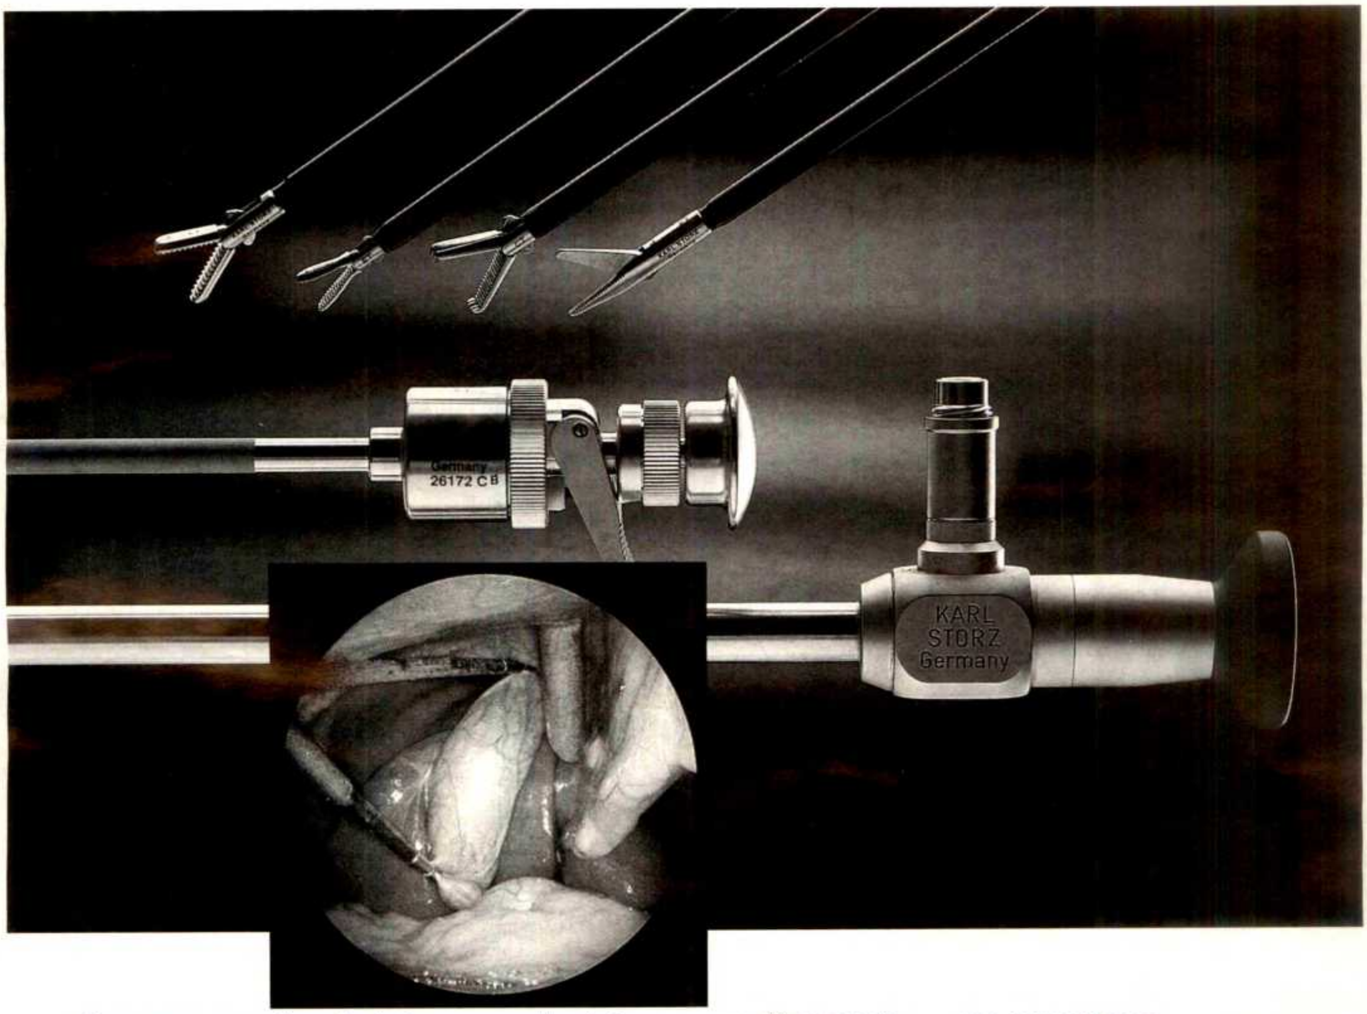
Minimally Invasive Surgery:
Laparoscopic Cholecystectomy.



Few new operating techniques have received such widespread and positive response in recent times as laparoscopic cholecystectomy. This is a clear indication that the advantages of this method are being recognized and accepted.

KARL STORZ instruments provide the surgeon with the optimal instrumentation for laparoscopic cholecystectomy. The proven and still unsurpassed quality of the Hopkins rod lens telescope and newly developed instruments, matched specifically to the requirements of endoscopic gall bladder removal, complement each other to form a range of instuments which meets all requirements in terms of precision, reliability and userfriendliness. An extensive wealth of experience and the capability of solving problems creatively also make KARL STORZ a reliable partner for the surgeon in laparoscopic cholecystectomy.

Surgery of the Anus, Rectum and Colon

M.R.B. Keighley & N.S. Williams

Surgery of the Anus, Rectum and Colon is without question a textbook of exceptional detail and clarity and will, like its classic predecessor by John Goligher from the same publisher, prove to be a landmark in the surgical literature.

2 Volume Set 0702012785 September 1993 c 2,000 pages c £280.00

Surgery for Congenital Heart Defects 2/e

J. Stark & M. deLeval

The most comprehensive resource on operative procedures for congenital cardiac defects has been extensively revised. More than 50 experts describe their techniques in complete detail, including small but often important technical aspects usually not covered in other surgical references.

0721636489 October 1993 c 608 pages c 741ills c £188.00

Atlas of General Surgery

D.C. Sabiston

This new **Atlas of General Surgery** is a current, comprehensive "see and do" guide to 100 of today's most significant operations - including laparoscopic techniques and gynaecological procedures. Readers will find it an essential resource for using the experts' techniques with ease and success.

0721678831 December 1993 c 928 pages c 800 illusc £115.00

Gastroenterology, Clinical Science and Practice, 2/e

I.A.D. Bouchier

Completely revised and updated by an international team of contributors, this second edition is a comprehensive reference for all clinicians interested in gastrointestinal disease. By including a surgeon as an editor and surgical contributors it provides a more rounded view of gastroenterology than is often found in textbooks.

2 Volume Set 0702015008 September 1993 c 1,400 pages c £175.00

Surgery for Stroke

R. Greenhalgh

An authoritative, multi-author, state-of-the-art review of a controversial field, **Surgery for Stroke** covers the indications for carotid surgery - now re-evaluated in the light of International Clinical trials; it describes all the best techniques of carotid surgery and justification for individual approach; it also covers intra-monitoring assessment methods and assesses their contribution to the reduction of intra-operative stroke.

0702017590 April 1993 420 pages 177ills £75.00

Atlas of Vascular Surgery: Basic Techniques and Exposures

R. B. Rutherford

A comprehensive, two-volume atlas which depicts the entire spectrum of vascular surgery from the basics to the most complex vascular procedures. With over 600 detailed illustrations, this atlas covers all aspects of vascular surgery, laying the groundwork for understanding the entire spectrum of specific procedures.

0721629563 April 1993 288 pages 155 illus £57.00

Vascular Surgery: A Comprehensive Review 4/e

W.S. Moore

The fourth edition of the book that surveys the entire field of vascular surger in a clear concise fashion. It covers all elements of vascular surgery along with the newest developments. New chapters have been included on vasculogenic impotence, natural history and non-operative treatment for chronic lower extremity ischemia, evaluation of cardiac risk in patients with vascular disease, myointimalhyperplasia. All other chapters have been revised and updated.

DIAGNOSTIC AND THERAPEUTIC ENDOSCOPY

EDITOR IN CHIEF
HARUBUMI KATO, Department of Surgery,
Tokyo Medical College, 6-7-1 Nishishinjuku,
Shinjuku-ku, Tokyo 160, Japan

AIMS & SCOPE
Diagnostic and Therapeutic Endoscopy aims to publish a variety of articles on all aspects related to endoscopic procedures in the areas of ENT, lung, esophagus, upper GI, hepatopancreatobiliary tract, lower GI, urinary bladder, uterus, cervix, joints, vessels, thoracic and abdominal cavities. The journal will initially be published quarterly and will guarantee high quality photography. Articles on preclinical and clinical research, case reports, as well as description of the development of equipment and accessories will be given priority. Retrospective reviews and papers with negative results may also be accepted in certain cases and every effort for prompt processing for publication will be made.

What every surgeon should know...

Thromboembolic complications still remain a common problem after surgery.[1] A number of studies have shown that the risk of thromboembolic complications after surgery can be significantly reduced by thromboprophylaxis.[2]

The introduction of Fragmin now makes this treatment even more convenient[3] and effective[4] than with Unfractioned Heparin.

...Fragmin simply Once-a-Day Effective thromboprophylaxis

Actual size of syringe.
Prefilled syringes in two concentrations
2,500 IU and 5,000 IU.

Fragmin®
dalteparin sodium

Kabi Pharmacia
Cardiovascular

Fragmin® Abbreviated Prescribing Information.

Presentation: Single dose disposable syringes containing dalteparin sodium 2,500 IU (anti-Factor Xa)/0.2 ml or 5,000 IU (anti-Factor Xa)/0.2 ml. No preservative present. **Indication:** Peri- and post-operative surgical thromboprophylaxis. **Dosage:** Adults only. Moderate risk of thrombosis. Fragmin 2,500 IU administered subcutaneously (sc) 1—2 hours prior to surgery and thereafter 2,500 IU sc once-daily for five days or until the patient is fully ambulant. High risk of thrombosis eg elective hip replacement, extensive operations, patients with malignant disease. Fragmin 2,500 IU administered sc 1—2 hours prior to surgery, and the same dose is administered 12 hours later. Thereafter 5,000 IU sc once-daily for five days or until the patient is fully ambulant. **Contraindications:** There are no known absolute contraindications to Fragmin. However, caution should be exercised in patients with an increased risk of bleeding complications. **Precautions:** Caution in patients with severely disturbed hepatic or renal function, thrombocytopenia, or defective platelet function and in patients receiving drugs affecting coagulation/platelet function; patients with known heparin hypersensitivity. Fragmin, when administered in doses of 2,500—5,000 IU/day, does not generally accumulate and, therefore, monitoring of anti-Factor Xa levels is not usually necessary. **Side effects:** High doses of Fragmin with serum anti-Factor Xa levels greater than 1.5 IU/ml may cause bleeding. Transient slight to moderate increase in liver enzymes have been observed. The following heparin side effects cannot be excluded as Fragmin is a derivative of heparin: thrombocytopenia, allergic reactions, osteoporosis. **Overdose:** 100 IU Fragmin is inhibited by 1 mg protamine: see data sheet for full prescribing information. **Legal Category:** POM. **Packs:** Fragmin 2,500 IU/0.2 ml; pack of 10 single dose syringes. 5,000 IU/0.2 ml: pack of 10 single dose syringes. **P L Numbers:** 2,500 IU/0.2 ml 0022/0076. 5,000 IU/0.2 ml 0022/0077. **Kabi Pharmacia Ltd, Davy Avenue, Knowlhill, Milton Keynes, MK5 8PH.**

Eurosurgery 93

The Editors once again welcome Eurosurgery to our pages, in the publication this month of a supplement containing abstracts of papers presented at the Eurosurgery 93 meeting in London. This 3rd European Congress of Surgery unites specialists from all surgical disciplines in a single forum to discuss matters of common interest such as training in surgery, specialization, new techniques and research, as well as practical aspects of their own specialty. Once again, the quality and diversity of the abstracts included in the supplement speak for the excellence and variety of European surgery and its associated research activities.

Papers from Eurosurgery 92 were published in a special issue of the Journal in March 1993. The Editors hope that once again contributors to Eurosurgery 93 will give *The British Journal of Surgery* the opportunity to publish their work. Authors who wish to submit a paper may do so at the meeting, or directly to the Journal office (please note our new address) before the end of September. We hope that the papers selected for publication will appear in the Journal in the Spring of next year.

The Editors wish every success to Eurosurgery 93.

R. C. N. Williamson
J. R. Farndon
J. A. Murie
C. D. Johnson

Overseas Members of the Editorial Board

Br. J. Surg. 1993, Vol. 80,
September, 1090–1091

Further Board Members from around the world.

DR HENRY PITT
(USA)

Henry Pitt (born 1945) is Professor and Vice-Chairman, Department of Surgery, the Johns Hopkins Medical Institution, Baltimore, Maryland. He went to medical school at Cornell University, did his surgical training at Johns Hopkins and worked in Los Angeles before returning to the East coast. He has been Secretary of the Society of University Surgeons and of the Society of Clinical Surgery. He is well known for his work on biliary sepsis, obstructive jaundice and pancreatectomy.

MR BRUCE WAXMAN
(Australia)

Bruce Philip Waxman (born 1949) is Senior Lecturer in Surgery and Clinical Sub-Dean at Monash University, Victoria. Graduating from the Alfred Hospital, Melbourne, he trained in England, Australia and the USA, and has held consultant posts in several Melbourne hospitals. His clinical interests include colorectal surgery, trauma and surgical nutrition. He is heavily involved in undergraduate and postgraduate teaching, and is a Councillor with the Royal Flying Doctor Service of Australia.

PROFESSOR ROLLAND PARC
(France)

Rolland François Parc (born 1940) is Clinical Professor and Chairman of the Department of Gastrointestinal Surgery at Saint-Antoine Hospital, University Paris VI. His medical education and surgical training took place in the hospitals of Paris. He is Associate Editor of *Annales de Chirurgie* and *Hepatogastroenterology*. His particular clinical interest is in colorectal surgery, and he has just been elected an Honorary Fellow of The Royal College of Surgeons of England.

0007-1323/93/091090-02 © 1993 Butterworth-Heinemann Ltd

PROFESSOR ANGELITA HABR-GAMA
(Brazil)

Angelita Habr-Gama is Professor of Surgery and head of the Colorectal Surgery Unit at the Hospital das Clinicas of the School of Medicine of the University of São Paulo. She qualified as a doctor at the University of São Paulo. Her special interest is colorectal surgery, particularly sphincter-saving operations for the treatment of rectal cancer. She was elected President of the Brazilian Society of Coloproctology in 1981 and is President of the Latin American Association of Coloproctology. She is also Vice-President of the Brazilian College of Surgeons.

PROFESSOR EMMANUEL ELEBUTE
(Nigeria)

Emmanuel Adeyemo Elebute graduated from Trinity College, Dublin, and trained at Birmingham Accident Hospital, the Hammersmith and the Royal National Orthopaedic Hospital, Stanmore. He became Professor of Surgery in Lagos in 1969 and Provost of the College of Medicine in 1977. He has served as Secretary-General of the West African College of Surgeons and President of the Nigeria Medical Association. He is particularly interested in oesophageal and breast surgery plus sepsis and metabolism.

DR LUIS DA MOTA CAPITAO
(Portugal)

Luis A. L. da Mota Capitao was born in 1950. He graduated and did his surgical training in Lisbon apart from a year in the Vascular Surgical Unit at St Mary's Hospital, London. In 1990 he was appointed consultant surgeon at St Marta Hospital, Lisbon, and he is responsible for the Vascular Surgical Unit at S. Jose Hospital in that city. Within vascular surgery his main interests lie in aortoiliac and femorodistal bypass, critical ischaemia and carotid pathology.

PROFESSOR A. P. R. ALUWIHARE
(Sri Lanka)

A. P. R. Aluwihare (born 1939) is Professor of Surgery and former Vice-Chancellor of the University of Kandy, Sri Lanka. His medical education was at Cambridge University and the London Hospital, and he trained in England before returning to Sri Lanka. He held a Hunterian Professorship at The Royal College of Surgeons of England and is a Fellow of the National Academy of Sciences in Sri Lanka. His special interests include paediatric and colorectal surgery.

Genetic testing for multiple endocrine neoplasia

In recent years it has been recognized that the neoplastic transformation of a somatic cell results from a defect, or combination of defects, at the genetic level. The study of certain familial diseases, such as the multiple endocrine neoplasia (MEN) syndromes, has identified specific chromosomal loci that appear to be pivotal in the development, not only of the inherited tumours, but of their sporadic counterparts as well.

Virtually all patients with MEN type 1 have parathyroid hyperplasia at the time of diagnosis; less than half have pancreatic islet cell tumours (usually gastrinomas) and less than one-quarter have pituitary tumours (usually prolactinomas). Occasionally these patients also develop adenomas of the thyroid gland or adrenal cortex. The MEN 1 gene has been assigned to a specific segment on the proximal long arm of chromosome 11 by genetic mapping[1], but to date the nature of this gene and the specific mutation(s) responsible for the syndrome have not been defined. Using molecular genetic techniques one can demonstrate, in DNA from both parathyroid and pancreatic islet cell tumours, allelic deletion of the portion of chromosome 11 harbouring the MEN 1 locus[1]. Furthermore, the deletion always affects the chromosome derived from the unaffected parent, thus allowing expression of the germline mutation that is inherited on the chromosome from the affected parent. This pattern is consistent with a 'two-hit' model of tumorigenesis, which involves mutation or loss of both homologues of the putative MEN 1 tumour suppressor gene. Although the MEN 1 mutation remains undiscovered, highly accurate DNA-based genetic testing[2] is possible based on the inheritance pattern of certain genetic markers situated very close to the position of the MEN 1 gene on chromosome 11. The clinical role of early genetic diagnosis of MEN 1 gene carriers is not clear, however, because surgical treatment for parathyroid hyperplasia, pancreatic islet cell neoplasia or pituitary neoplasia should not be undertaken until a clinical and biochemical diagnosis of the specific endocrine tumour has been established.

Virtually all patients with MEN 2A develop medullary thyroid carcinoma (MTC); approximately half will develop clinical or biochemical evidence of either phaeochromocytoma or parathyroid hyperplasia. Patients with the rare MEN 2B syndrome have MTC, phaeochromocytoma, mucosal neuroma and ganglioneuromatosis of the gastrointestinal tract. They also have a characteristic phenotype. Patients with familial MTC inherit only MTC and have none of the extrathyroid manifestations characteristic of MEN 2A or 2B.

Until recently, the standard for early diagnosis of MTC in patients at risk for MEN 2A was the measurement of plasma calcitonin levels by radioimmunoassay following stimulation with the calcitonin secretagogues calcium and pentagastrin[3]. The demonstration that the gene(s) for the distinct clinical syndromes MEN 2A, MEN 2B and familial MTC[4–7] each map to the centromere region of chromosome 10 was followed by the advent of DNA-based testing to identify individuals who have inherited the disease mutation before the time that they manifested either clinical or biochemical evidence of MTC[8,9].

Very recently, work in our own and other laboratories[10,11] has identified germline mutations in the *RET* proto-oncogene, a tyrosine kinase receptor gene on chromosome 10. These mutations are associated with the MEN 2A and familial MTC syndromes. Mulligan and co-workers[10] identified missense mutations in 20 of 23 apparently distinct families with MEN 2A. Similarly, Donis-Keller and colleagues[11] identified 12 different mutations in the germline DNA and tumour DNA from patients with MEN 2A and familial MTC. Each of the mutations described in these studies involves a codon for a highly conserved cysteine residue within the extracellular domain of the *RET* proto-oncogene tyrosine kinase receptor. This results in an amino acid substitution that presumably adversely affects the structure of the extracellular receptor portion of the molecule. The precise function and the ligand of the protein

---

Professor Wells gave the Peter Heimann Lecture on this subject to the International Association of Endocrine Surgeons in Hong Kong, August 1993

0007-1323/93/091092-02 © 1993 Butterworth-Heinemann Ltd

encoded by the *RET* proto-oncogene are not currently known. More importantly, the reason for the tissue specificity of neoplasia resulting from this germline mutation, which is present in every cell in the body, has not been elucidated. In contrast to MEN 1, there is no evidence of consistent allelic deletion of *RET* in the DNA from either the MTCs or phaeochromocytomas that develop in these patients. Patients with MEN 2A have been found to be heterozygous (i.e. retain one normal allele) for *RET* missense mutations in both germline *and* tumour DNA. If the mutations described cause the MEN 2A syndrome, then *RET* apparently acts as a dominant oncogene in the development of neoplasia in tissues derived from the neural crest.

It is interesting to note that mutations resulting in amino acid changes in the same cysteine codon are apparently responsible for the distinct clinical syndromes of MEN 2A and familial MTC. It has been postulated that other genes could modify the spectrum of expression or age of onset in different families. Although it seems likely that defects in the *RET* proto-oncogene are also responsible for the MEN 2B syndrome, mutations have not been found to date in the exons involved in MEN 2A or familial MTC. The possibility that a mutation in a contiguous gene results in the MEN 2B syndrome cannot be excluded. Finally, in the combined reports above six families with MEN 2A have been studied in which the mutations have not been detected and presumably lie within other exons not yet examined. The eventual detection of all the mutations within *RET* that would predict disease, and the implementation of an efficient means of making a genetic diagnosis, will almost certainly introduce important new issues in the management of family members at risk of these disorders.

Diathermy in laparoscopic surgery

The safety of monopolar radiofrequency electrical energy has been proven by 50 years of use during laparotomy. But how much do we know about diathermy and does its use differ in laparoscopic surgery?

Alternating current, the type used for surgical diathermy, is characterized by power output (the rate of power delivered at a given time) and frequency modulation. The latter refers to the number of changes in the direction of the current within 1 s and how this number changes over time. Empirically, it has been found that certain frequencies are more appropriate when cutting or coagulation is desired.

'Polarity' (monopolar *versus* bipolar) refers to the number of electrical poles at the site of application; the main difference is the distance between the poles. For monopolar, the second pole is the dispersive electrode plate, usually attached to the patient's thigh. In bipolar mode, the distance between the poles is a few millimetres and the current affects only the tissue located between these poles. Relatively low power is needed in bipolar mode; up to ten times more is required in monopolar mode because the body is a poor electrical conductor. The relatively low power of bipolar diathermy is insufficient to obtain the power density required to cut tissue. This power density is the key element that determines the thermodynamic effect. In general, a highly concentrated electrical field leads to vaporization (cutting) of tissue and a more dispersed field results in coagulation. It is possible to manipulate this bioeffect of electrical current only in the monopolar mode, although recent advances in bipolar technology may have overcome this problem[1]. Changing between, or combining, cutting and coagulation is usually achieved via a switch on the diathermy machine, but the surgeon may change the contact area at the point of dissection to convert a high-power 'cutting' output to 'coagulation' by holding, for example, a forceps between diathermy instrument and tissue, thereby reducing the power density.

Monopolar electrical energy is the most frequently used method of dissection in laparoscopic surgery today. Lasers have been readily adapted to laparoscopic surgery but have no proven safety benefit over the less expensive and more freely available electrocautery systems[2]. Laser dissection methods rely on the ability of light energy to excite molecules sufficient to cause heating of the recipient tissue and disruption of structural proteins[3]. Carbon dioxide laser dissection, in particular, has an inherent 'backstop effect' that is difficult to control and may lead to inadvertent damage of structures adjacent to the area of intended coagulation[4]. Newer technology using the neodymium yttrium–aluminium–garnet laser with contact tips has eliminated the danger of a free beam loose in a body cavity, but energy penetrates deeply (3–4 mm) and may injure adjacent tissue inadvertently.

The potential problems associated with the laparoscopic use of monopolar electrocoagulation are not fully appreciated[5]. They relate to unrecognized energy transfer ('stray current') outside the view of the laparoscope. During laparoscopic surgery electrical energy is passed through the abdominal wall via cannulas (which themselves may or may not be conductors) by instruments (which may or may not be adequately insulated) to tissues being dissected. The only part of this circuit that is visible is the tissue being dissected. Potential areas for concern include insulation breaks, induced currents between a correctly insulated instrument and its surrounding cannula (capacitative coupling), unintended contact with other metal instruments within the abdomen (direct coupling), energy transfer through tissue from the point of dissection, and arcing (sparking) to local structures from a dissecting electrode that has been activated but is not in contact with the body. Therefore, electrical injury remote from the site of surgery may occur as a result of tissue conduction, discharge of induced capacitative coupled current, and high-voltage sparking. Hunter[1], and Voyles and Tucker[5] recently addressed the problems of stray current outside the view of the laparoscope.

Insulation defects, although frequently not visually perceptible, may lead to near 100 per cent delivery of electrical energy at a site beyond the view of the laparoscope. The hazard of insulation failure depends on the location of the point of failure along the instrument. If in the handle, it may cause a shock to the surgeon. If outside the view of the camera, thermal injury may occur to any viscus in contact with the defective instrument. If it occurs within the metal cannula, the only evidence may be interference with the electrosurgical generator, jerking of the abdominal wall, or interference with the video monitor. This may be harmless as the current is dissipated

0007-1323/93/091094-03 © 1993 Butterworth-Heinemann Ltd

by broad contact at the abdominal wall. If, however, the defective instrument is within a plastic cannula, there may be no clue to insulation failure. It is important that single-use instruments are not resterilized as this can lead to insulation breaks and inadvertent direct coupling.

Capacitative coupling can lead to laparoscopic complications, although the likelihood is remote. Current is induced in the metal cannula through which the dissecting instrument passes and may be transmitted to tissue outside the view of the laparoscope. Current is greater if 5-mm rather than larger diameter cannulas are used and if they are covered by a plastic tissue anchor. In the latter situation the cannula is isolated from the abdominal wall, preventing electrical dissipation through the dispersive electrode.

Electrical energy dissipated through tissue has the ability to cause distant necrosis that may become apparent only some time after surgery. The temperature generated by an electrical current is inversely proportional to the fourth power of the diameter of the body along which it is conducted. Structures of small diameter are, therefore, at risk of necrosis and subsequent perforation or stricture if they are in the line of current dispersion. For example, if the diameter of the appendix base is reduced by half with a ligature and the structure then divided using diathermy, the current density at the ligature will be four times greater than at the point of contact and the temperature increase will be 16 times greater, which may result in necrosis and perforation[1].

Arcing occurs when a high-voltage current jumps the distance between the electrode and nearest body tissue. This sparking discharge may occur if the electrode is left active but not in contact with the point of dissection and is proportional to voltage. The diathermy peak-to-peak potential difference should be less than 1200 V. Although considerable variation exists, diathermy machines that are more than 5 years old may be able to generate a peak-to-peak potential difference of 6000 V. Such a discharge can produce necrosis at the contact point of the spark.

In addition to the hazards of electrical current in diathermy dissection, the tip of an activated electrode generates substantial heat energy. If the active electrode is not in contact with tissue, a temperature of over 500°C can be generated, as the heat cannot be rapidly dissipated. If it touches a viscus, a thermal burn may result even after the diathermy has been made inactive[6]. If monopolar electrocoagulation is to continue as the preferred mode of dissection in laparoscopic surgery it is essential that surgeons understand its method of action and potential pitfalls.

What of non-laser alternatives to monopolar dissection? High-frequency ultrasonic coagulation[7] holds considerable promise as a cutting and coagulating energy source adapted for laparoscopic use. A piezoelectric transducer is housed in a handpiece causing a blade tip to vibrate at 55 kHz with a 50-μm excursion. The mechanical energy causes cutting and coagulation by vibrational forces; this cavitational effect vaporizes intracellular water and disrupts cell walls. Maximum blade temperatures do not exceed 80°C and the spread of necrosis from the point of contact (in the epidermis) is less than 0·05 mm, compared with 0·35 mm for electrothermal necrosis[8]. The technique of water-jet dissection has been used in hepatobiliary surgery selectively to dissect liver parenchyma while leaving vessels and ducts intact for subsequent ligation or coagulation. High- and low-pressure systems exist that deliver a jet of water of between 0·06 and 0·25 mm in diameter at 15–50 and 200–1000 bar (1500–5000 kPa and 20 000–100 000 kPa) respectively. Tissue penetration is decreased by increasing the distance between the jet nozzle and dissection area until the stream velocity is insufficient for cutting[9]. These innovative techniques promise an exciting future but they are not yet fully refined for laparoscopic surgery. It is possible that electrosurgery will be replaced by these methods but, until then, didactic lectures in monopolar electrocoagulation should be an integral part of training programmes in laparoscopic surgery.

Announcement

European Surgical Fellowships

The Council of *The British Journal of Surgery* is pleased to announce the availability of European Surgical Fellowships for 1994. Last year four Fellowships were awarded, to Dr Jose Luis Aguayo-Albasini (Spain), Mr R. M. Charnley (Nottingham), Mr S. D. Heys (Aberdeen) and Mr T. G. John (Edinburgh).

It is Council's intention to offer European Surgical Fellowships again in 1994. Each Fellowship will have a value of up to £3000 and is intended to allow surgeons working in the UK to visit centres in other European countries or surgeons working in other European countries to visit the UK. Applicants must be under 40 years of age and should submit details of their proposed itinerary and its anticipated cost, together with a copy of their *curriculum vitae* and two letters of support from senior colleagues. They should explain briefly how such a visit might broaden their experience and assist their career. Fellowships will not be awarded solely for the purpose of attending courses or meetings.

Applications should be sent to the Company Secretary, Professor D. C. Carter, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, by 1 February 1994.

Silicone gel breast implants, breast cancer and connective tissue disorders

A. J. Park, R. J. Black* and A. C. H. Watson

Recent worldwide media speculation that silicone gel-filled breast implants may be linked to an increased incidence of breast and other cancers, and connective tissue disease (particularly systemic sclerosis) has caused concern to the medical profession and public alike. Until carefully controlled studies have been performed to prove the safety of these implants, the US Food and Drug Administration has restricted their use to research and breast reconstruction. Research has so far failed to prove a causative relationship between silicone implants and cancer or connective tissue disorders.

The recent widespread media speculation that silicone implants may be linked to breast and other cancers, and to connective tissue disease – particularly systemic sclerosis – has highlighted a current cause for anxiety to both the medical profession and the public.

Surgical implantation of plastic materials for reconstruction or augmentation of the breast has become popular following the development in 1963 of the modern silicone implant[1]. Before the use of implants, developmental abnormalities of the breast were corrected by less satisfactory means using transplanted fat tissue, implantation of other synthetic materials such as polyvinyl alcohol, or injection of silicone or paraffin.

At least 2 million women in the USA now have silicone gel-filled implants. These are used for reconstruction following mastectomy for breast cancer, or to enlarge or reshape the breast for cosmetic purposes. The psychological benefits of these procedures are well recognized[2–4].

Silicones have never been found in nature, although they are derived from quartz or silica (SiO_2). They can be synthesized as viscous fluids, watery liquids, compounds, resins and rubber-like products[5]. Silicon is an abundant element in nature, foods and man-made products. It comprises 27 per cent of the Earth's crust; only oxygen, at 48 per cent, is more abundant. Large amounts of silicon are ingested in drinking water and it is an essential element for plants and probably also for mammals, including humans[6].

Silicone is composed of long chains of dimethylsiloxy groups; the longer the chain, the more viscous the fluid[5]. It is one of the least inflammatory of implanted alloplastic biomaterials[7]. The relative stability, non-reactivity and hydrophobic qualities of silicone in tissues proved valuable for many uses, ranging from lubrication of needles and syringes to coating of implantable devices such as penile implants, hip-joint prostheses and finger-joint prostheses. It has proved useful in an almost infinite range of physical forms, from oils and gels to soft and firm rubbers.

Silicone breast implants consist of a silicone elastomer shell that may be filled with a silicone gel by the manufacturer or with saline by the surgeon at the time of implantation (*Figures 1* and *2*). The silicone shell contains silica as a filler necessary for strength; silica is not present in the gel. In tissues, silica can cause silicosis, but whether it is released into the surrounding tissue from the prosthetic shell is not known[8].

The silicone elastomer is a semipermeable membrane and as such allows the gel to pass from the implant into the surrounding tissue by diffusion. This is known as 'bleed' and has been observed by many researchers[9–11]. Implant bleed can be seen by placing a gel-filled prosthesis on a paper towel: in just a few hours a sticky oily stain can be seen. Wickham *et al.*[12] used scanning electron microscopy to prove that the droplets in fibrous capsule biopsies contained silicone. Rudolph *et al.*[8] demonstrated that such droplets occur only around gel-filled implants, suggesting that the silicone came from the gel and not from the surrounding capsule. However, the presence of these droplets did not correlate with the clinical findings of a firm breast[8,13]. Silicone has also been noted in the surrounding capsule when saline-filled implants were used, but to a lesser extent[14]. It has also been found in sites distant

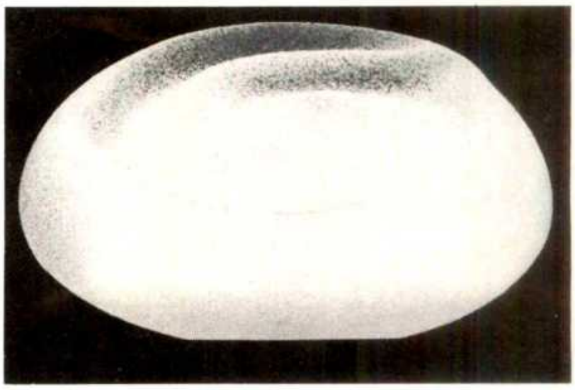

Figure 1 *Textured silicone gel-filled breast implant*

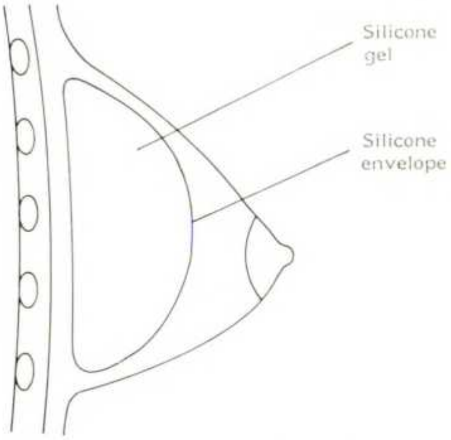

Figure 2 *Cross-section of the chest wall showing a breast implant* in situ

0007-1323/93/091097-04 © 1993 Butterworth-Heinemann Ltd

from the implant such as the antecubital fossa[15], upper arm[16,17], chest and shoulder[17], and abdominal wall as far as the groin[18]. Rupture of the implant was evident in all these cases.

The surrounding tissue generally reacts with a mild transitory inflammatory response, without evidence of the chronic inflammation associated with toxicity or the antibody formation and plasma cell infiltration associated with an immune response. The tissue reaction is characterized from the first to third days by an infiltration of neutrophils, a few plasma cells and macrophages. By days 6–7 the number of leucocytes is significantly decreased and a band of fibroblasts surrounds the silicone. A fibrous capsule progressively develops over the next 2–3 weeks. The deposition of this relatively acellular layer of connective tissue has been described as the normal wound-healing response to a large inert foreign body in a sterile environment[19]. Breast implants always produce a surrounding fibrous capsule, following which there is little tissue reaction[20]. This inflammatory response is often associated with a degree of capsular contraction that in almost 10 per cent of cases causes sufficient discomfort and distortion of the breast to require secondary surgery. Myofibroblasts have been detected within the capsule and may be the cause of the contracture[8]. If the implant ruptures, the capsule is found to be thicker[21].

Capsular contraction is the most frequent complication of breast augmentation[22,23]. With the original smooth-walled implants there was a 30–50 per cent incidence of significant contracture[24–26]; textured implants cause less capsular contraction than smooth-walled prostheses[25,27,28]. A similar improvement was seen with the use of polyurethane-coated implants[29–31] but these have been withdrawn from the market after allegations that they are carcinogenic because of the breakdown of the polyurethane coating to 2,4-toluene diamine. Capsular contraction is found when saline-filled implants are used but to a lesser extent than that associated with silicone gell-filled prostheses[32]. The newer low-bleed implants show a lower contracture rate than conventional devices[33].

Recommended methods of preventing contracture include atraumatic technique[34,35], areolar incision[36,37], submuscular placement of the prosthesis[37], wide surgical pocket[35,38], double-lumen prosthesis[39], local cortisone[39,40], routine administration of antibiotics[40–42], vitamin E[43], and rapid and late mobilization[23,40] by bandage or massage of the implant. While there is no way of avoiding this complication completely, the newer low-bleed textured gel implants seem to have reduced the incidence of capsular contracture to a useful degree.

Carcinogenicity

In 1953, Oppenheimer *et al.*[44] reported the development of sarcoma in Wistar, Sherman, Longacre, Paris and C57 strains of rat after plastic had been embedded. In 1955, silicone was added to the list of solid materials presumed to be the stimulus for sarcoma development[45]. Rats are known to be highly susceptible to sarcoma following exposure to carcinogens, but such tumours have not been induced in higher mammals[46,47]. At no time during these or any subsequent study has an increase in the incidence of breast adenocarcinoma attributable to silicone been observed.

A large number of women have now been exposed to silicone implants and any question of carcinogenicity must be viewed against the normal background of cancer in humans. The incidence of breast cancer in women is 1:10 in the USA and 1:12 in the UK[48]. Breast cancer has been reported in women with implants[1,46,47,49,50] but, as yet, there is no evidence that prostheses cause cancer or that breast cancer occurs with a greater frequency among women receiving augmentation than in the general population[51–53].

Two studies in the USA have suggested that the incidence of breast cancer is less in patients with implants[54,55]. In these studies, cancer registration data were used to ascertain breast cancer outcomes and to estimate breast cancer rates in the background population. Both studies found a lower than expected incidence of breast cancer in women with implants (relative risk 0·5 and 0·7 respectively), although in neither was this statistically significant. The study by Deapen and Brody[55] reported significantly higher incidences of lung (relative risk 2·1) and vulval (relative risk 5·3) cancer, although these arose in a survey of a range of cancer sites. These studies depended on the accuracy of linkage with a subnational cancer registry to determine outcomes. Bias may be introduced by, for example, unusual socioeconomic characteristics of the patients given augmentation relative to the background population; it could be that the former are more mobile and therefore more likely to move out of the study ascertainment area. This could be avoided in a matched cohort study in which both cases and controls are equally likely to be lost to follow-up, but no matched cohort or case–control study has been published.

Silverstein *et al.*[56] compared 20 previously augmented patients with breast cancer with 248 non-augmented controls with breast cancer. All 20 were cases of invasive tumour and the relative risk for nodal involvement at presentation was 1·9 for women with implants compared with those without augmentation. This apparent tendency for breast tumours to be detected later in cases than in controls is not consistent with earlier reports[1] from Deapen's cohort, in which the patients with breast cancer tended to have disease at an earlier stage at the time of diagnosis. The evidence to date suggests that implants are not a risk factor for breast cancer and that the survival rate among these women with cancer is no lower than expected.

Connective tissue disorders

Systemic sclerosis is an immune-mediated disorder of connective tissue characterized by overproduction of collagen leading to sclerotic changes in the skin and visceral organs. Typical of the disease are induration and thickening of the skin (scleroderma), Raynaud's phenomenon and other vascular abnormalities, musculoskeletal manifestations and visceral involvement, especially that of the gastrointestinal tract, lungs, heart and kidneys. In addition to systemic sclerosis, systemic lupus erythematosus, polymyositis, dermatomyositis, Raynaud's syndrome and rheumatoid arthritis have all been described in association with silicone implants. However, little is known about the aetiology of these diseases and associations include exposure to toxic oils, vinyl chloride, other solvents and resins, and silica among miners as well as augmentation mammoplasty. The incidence of systemic sclerosis in the general population[57–64] varies in different studies from 0·6 to 20 cases per million per year. The most recent report, a 20-year incidence study, found a mean annual incidence over the decade to 1982 of just under 20 cases per million population[64]. Systemic sclerosis is at least three times more common in women than men[57,64]. The prevalence of scleroderma is thought to be about 25 per 100 000 female population[65].

Connective tissue disorders have been reported to occur following cosmetic surgery (including breast augmentation) employing injection of foreign substances such as paraffin and silicone[66,67]. A great deal of alarm was caused recently by claims in the lay media that systemic sclerosis in particular, or connective tissue disease in general, may be caused by exposure to the silicone-containing implants used for breast augmentation or reconstruction. The suspicion of an association between autoimmune disease and silicone gel-filled breast implants has arisen from over 100 case reports; these have led some to believe that silicone might serve an 'adjuvant' role in the development of autoimmune disease. Much of this literature comes from Japan and, while the majority of cases resulted from injection of material such as paraffin or silicone of unknown origin and composition, there have been instances in which implants have been implicated[23,68–75]. A recent study in the USA found that patients with a defined autoimmune disorder and a silicone breast implant had high titres of antinuclear antibodies, and that the specificities of these antibodies were similar to those found in the idiopathic form of the relevant autoimmune disease. Trauma with resultant rupture of the prosthesis seems to accelerate the onset of symptoms and systemic sclerosis is the commonest disorder among patients with breast implants[76].

Despite many case reports in the literature, few epidemiological studies have been conducted. The risk of systemic sclerosis in women receiving implants for breast augmentation has been estimated in two reviews of case reports. However, Kondo *et al.*[77] and Shons and Schubert[78] presented grossly different estimates of the risk for augmented women relative to the background population: 3·0 and <0·1 respectively. This disparity is due in large part to different estimates of the background incidence of systemic sclerosis. Neither study attempted to use the conventional person-years of follow-up approach nor to calculate age-specific background rates. No properly controlled epidemiological study of systemic sclerosis in patients with augmentation or breast reconstruction has been published.

An independent advisory committee on silicone gel-filled breast implants was set up in Canada in February 1992. This committee found that the reported cases of so-called autoimmune disease in women with implants are proportionately far less numerous than in women without implants. They concluded that there is an absence of evidence that women with implants are more likely than those without to have an autoimmune disorder and that more research is required[79]. Until carefully controlled studies have been performed to prove the safety of silicone prostheses, the US Food and Drug Administration has banned their use for purely cosmetic indications but permits implantation in women with breast cancer, congenital disorders or traumatic injury. Although research has so far failed to prove that silicone gel-filled breast implants cause connective tissue disorders or cancer, work must continue as a question mark still remains over their safety.

Role of surgery in patients with primary non-Hodgkin's lymphoma of the stomach: an old problem revisited

The literature after 1980 dealing with the treatment of primary gastric non-Hodgkin's lymphoma (stages I and II) is reviewed. Gastrectomy is recommended for patients with acute symptoms at presentation or with complications of chemotherapy or radiotherapy. In elective cases, patients with stage I disease may be candidates for gastrectomy as a single therapy, provided that tumour-free resection margins are achieved. There is no evidence of substantial benefit from adding postoperative chemotherapy or radiotherapy after an apparently radical resection. In stage II disease, the best results are achieved with ablative surgery plus adjuvant therapy. The resection volume should be limited to macroscopically involved structures, in principle avoiding total gastrectomy and extensive lymph node dissection, since residual disease may be optimally controlled with radiotherapy or chemotherapy. Primary chemotherapy, with or without radiotherapy, represents an experimental approach; the advantages of sparing the stomach must be balanced against the toxicity of an aggressive chemotherapy regimen and the risk of emergency operation for iatrogenic complications.

Dr F. Bozzetti

Primary gastric lymphoma has long accounted for only 1–7 per cent of all malignancies of the stomach, but recent studies[1–4] indicate that its incidence is increasing. A recent report from the Surveillance Epidemiology and End Results Committee[4], which evaluated approximately 13 per cent of the total population of the USA, found a twofold increase in the age-adjusted incidence limited to people over 60 years of age.

The stomach is the commonest site of primary extranodal lymphoma[5–19]; it is even more commonly involved in the dissemination of nodal lymphoma[14,20,21]. Approximately one-sixth of patients with systemic disease have gastric involvement[22,23], but this rate may reach 50 per cent if necropsy series are taken into account[24].

The need for a periodic review of the role of surgery in the diagnosis and treatment of primary gastric non-Hodgkin's lymphoma derives from three assumptions. First, because of the rarity of the disease it is difficult for a single institution to accumulate enough experience to determine the best treatment. Second, the development of imaging techniques such as computed tomography (CT), magnetic resonance imaging and ultrasonography has substantially curtailed the indication for laparotomy for staging (if not for diagnosing) the disease. Third, the encouraging results obtained by using cytotoxic drugs on advanced lymphoma have prompted some groups to propose primary chemotherapy, even for early stages of the disease when the lymphoma is confined to the stomach and when surgical results are generally good.

A critical appraisal of the literature is difficult because most reports are retrospective and hence inherently biased, and many publications deal with gastrointestinal lymphoma and include patients with different sites (stomach and small or large bowel) and different stages of disease. Moreover, clinical staging and especially histopathological classification have changed over the years. To minimize such difficulties, this review considers mainly data[1–100] published since 1980 and focuses on the role of surgery in patients with lymphoma confined to the stomach (stages IE and IIE).

Pathology

Primary gastric non-Hodgkin's lymphoma has recently been defined as a clinicopathologically distinct entity that differs from non-Hodgkin's lymphoma of peripheral lymph nodes both in its clinical behaviour[55] and in its morphology. Isaacson *et al.*[60] have suggested that such extranodal lymphoma arises from lymphoid tissue that may develop at extranodal sites during inflammatory diseases – mucosa-associated lymphoid tissue (MALT) – and that neoplastic cells follow the familiar pattern of their normal counterparts and remain localized at extranodal organs[56]. Most MALT-derived lymphomas are of B cell origin; the tumours are composed of so-called centrocyte-like cells, so named because of their resemblance to centrocytes[57]. These cells appear to derive from lymphoid cells normally found at the periphery of the follicles of Peyer's patches and selectively infiltrate the dome epithelium[58]. A distinctive feature of centrocyte-like cells is their tendency to invade the mucosal epithelium and form characteristic lymphoepithelial lesions, with penetration into the wall of the mucosal crypts and eventual disruption of the epithelial structure. Centrocyte-like cells show immunoglobulin light-chain restriction but not *bcl2* gene rearrangement or the CD22^{+} CD23^{-} CD5^{-} CDw32^{+} CD43^{+} phenotype.

Other components that contribute to the histology of MALT gastric lymphoma are plasma cells, and lymphoplasmacytoid cells and follicles. The latter tend to be near the muscularis mucosae and beneath the centrocyte-like cell infiltrate. These neoplastic follicles are not composed of follicle centre cells but result from colonization of reactive follicles by centrocyte-like cells[59].

Owing to its derivation from a separate lineage of B cells, gastric MALT lymphoma does not fit into any of the categories described in commonly used classifications and formulations. Isaacson *et al.*[60] proposed a list of principal categories of primary gastrointestinal lymphoma (*Table 1*). In the stomach, in addition to low-grade B cell lymphoma of the MALT type,

Table 1 *Histopathological classification of primary gastrointestinal lymphoma*[60]

B cell
1. Low-grade B cell lymphoma of MALT
2. High-grade B cell lymphoma of MALT, with or without evidence of a low-grade component
3. Mediterranean lymphoma (immunoproliferative disease of the small intestine), low, mixed or high grade
4. Malignant lymphoma, centrocytic (lymphomatous polyposis)
5. Burkitt-like lymphoma
6. Other types of low- or high-grade lymphoma corresponding to peripheral lymph node equivalents

T cell
1. Enteropathy-associated T cell lymphoma
2. Other types unassociated with enteropathy

MALT, mucosa-associated lymphoid tissue

Table 2 *Staging systems for primary gastrointestinal non-Hodgkin's lymphoma*

Classification				
Ann Arbor[101]	Rao *et al.*[29]	Musshoff[102]	Description	Relative incidence (%)
IE	IE	IE	Tumour confined to gastrointestinal tract	26
IIE	IIE	IIE	Tumour with spread to regional lymph nodes	26
IIE	IIIE	IIE	Tumour with nodal involvement beyond regional lymph nodes (para-aortic, iliac)	17
IIIE–IV	IVE	IIIE–IV	Tumour with spread to other intra-abdominal organs (liver, spleen) or beyond abdomen (chest, bone marrow)	31

there are high-grade tumours composed mainly of centroblasts and in which there may be evidence of a low-grade residual component. Other types of non-Hodgkin's lymphoma corresponding to lymph node equivalents are rare.

Diagnosis and staging

A diagnosis of primary gastric lymphoma requires histological confirmation of a lymphoproliferative neoplasm in a clinical setting in which palpable adenopathy and hepatosplenomegaly are absent; there should be no evidence of lymphoma on chest radiography, CT, peripheral blood smear or bone marrow aspirate, and biopsy. The definition generally assumes the presence of symptoms referable to the upper gastrointestinal tract (abdominal pain, anorexia, nausea, vomiting), usually accompanied by an anatomically discernible lesion on double-contrast radiography or gastroscopy. Staging systems are shown in *Table 2*.

Contrast radiographic studies in patients with primary gastric lymphoma show various patterns, including a mass or filling defect in 71 per cent of cases. Ulcerative lesions are rare. A diffuse infiltrating process with thickened mucosal folds is seen in 20 per cent of cases[103–105]. These findings, while characteristic, are non-specific and often indistinguishable from other conditions such as gastric adenocarcinoma, Ménétrièr's disease, chronic gastritis and benign segmental hyper-rugosity. Because of this, a correct diagnosis of gastric lymphoma in the past has often required laparotomy. Early lesions may be mistaken for benign ulcers, and partial 'healing' of gastric lymphoma after H_2 antagonist therapy has been reported at endoscopy[44].

Recent evidence suggests that the accuracy of diagnosis by endoscopic biopsy is >90 per cent[63,64], but it is influenced by several factors. First, a lymphoma often grows in the submucosa and invades the mucosa only later in its course. Second, large ulcerating lesions may exfoliate necrotic material, which is difficult to interpret histologically. Third, when only small numbers of cells are available, a differential diagnosis between lymphoma and anaplastic carcinoma, or between small cell lymphoma and pseudolymphoma, is often impossible.

Since patients with proven gastric lymphoma are now subjected to an extensive diagnostic assessment that includes (besides careful clinical examination) CT of the lungs and abdomen, bone marrow aspirate and biopsy, and indirect laryngoscopy, it is unlikely that surgical exploration of the abdominal cavity would lead to a significant change in the staging of the disease. Staging laparotomy is, consequently, no longer recommended, even though the accuracy of CT in imaging regional gastric nodes is limited and may result in some understaging of patients[61,65]. However, if the surgeon embarks on a laparotomy because a preoperative histological diagnosis is lacking, diagnostic sampling of the liver, spleen, and mesenteric and retroperitoneal nodes is required in addition to gastric resection.

Emergency surgery at clinical presentation

Surgery may be required as an emergency procedure in patients with lesions that are obstructing, bleeding or perforated. *Table 3* describes the prevalence of features that might necessitate emergency surgery. The figures are somewhat biased because the criteria used to define bleeding and obstruction are not

uniform in the literature, and tertiary referral centres for oncological therapy tend to underestimate the true prevalence of acute symptoms. The prevalence of bleeding in the literature is 20–30 per cent; lower rates of perforation and obstruction (occasionally higher values) have been reported[38,40,49,50]. Severe bleeding or perforation requiring immediate surgery occurred in 10 per cent of the present authors' patients with stage I or II lymphoma[62].

Subtotal gastric resection is preferable in patients requiring emergency operation. Simple suture of a perforated wall, even if patched with omentum, or simple ligation of the gastric vessels in bleeding lesions are procedures to be adopted only if the stomach cannot be resected. Proper healing cannot be expected in neoplastic tissue and further perforation is likely to occur as soon as radiotherapy or chemotherapy begins. Moreover, the abundant blood supply of the stomach makes ligation of the vascular pedicles of uncertain benefit. In patients with an obstruction of the stomach outlet, resection is preferred to simple gastrojejunostomy or catheter jejunostomy, since removal of the stomach may provide a cure and obviates the subsequent risk of bleeding and perforation during medical therapy.

Emergency surgery during chemotherapy or radiotherapy

Several authors, including both surgical and medical oncologists, have advocated early surgery, before chemotherapy or radiotherapy, to eliminate the risk of bleeding or perforation associated with the destruction of tumour tissue in the gastric wall[9,14,18,19,30,58,67]. Data on the prevalence of such complications in the literature of the past decade are summarized in *Table 4*. Haemorrhage is associated both with chemotherapy alone (usually cyclophosphamide, doxorubicin, vincristine and prednisone (CHOP), with or without bleomycin) and when combined with radiotherapy, with a prevalence between 11 and 20 per cent[27,68]. Perforation is reported after chemotherapy or radiotherapy in a variable proportion of patients, ranging from 0 to 10–20 per cent[27,68].

Risk factors for such complications have not been adequately elucidated. Perforation probably occurs more often when the entire thickness of the gastric wall is involved (a condition now well recognized by endoscopic ultrasonography)[41,69–71], whereas haemorrhage may be more likely in ulcerative lesions. Concurrent thrombocytopenia may make haemorrhage more frequent and more difficult to manage. The presence of leukopenia may similarly increase the operative risk in patients requiring emergency surgery. In the present authors' experience, the mortality rate for elective subtotal or total gastrectomy is 6–7 per cent, but one of two patients submitted to emergency operation died[62].

Surgery as a therapy

The results of surgery are shown in *Table 5*. These are somewhat biased because they do not include patients who have undergone simple laparotomy or bypass (the resectability rate ranges from 66 to 88 per cent[13,43,44]). It is therefore difficult to compare the surgical results with those of alternative treatments such as chemotherapy or radiotherapy. A common finding is that surgical resection alone is associated with a 5-year survival rate >80 per cent in the largest series of patients with stage IE disease. At this stage the prognosis is little affected by the addition of radiotherapy, but the addition of postoperative chemotherapy appears further to improve the results. However, caution is required before drawing definite conclusions because the combination of surgery, chemotherapy and radiotherapy gave poor results in the experience of Maor *et al.*[26]. Experience with radiotherapy or chemotherapy alone is very limited; results are no better and possibly worse than with surgery alone.

For patients with gastric lymphoma of stage IIE, the prognosis is improved by 50 per cent if surgery is followed by chemotherapy, radiotherapy or both. The 5-year survival rate of patients treated by surgery alone is about 40 per cent; this figure reaches 60–70 per cent in larger series in which radiotherapy[18,23] or chemotherapy[25,27] was combined with gastrectomy. As in patients with stage IE disease, the efficacy of non-surgical therapy is controversial; results of only a few studies are available.

It could be concluded, from analysis of the literature on stage IE gastric lymphoma, that ablative surgery – alone, combined with chemotherapy, or with chemotherapy plus radiotherapy – is the therapeutic approach most frequently associated with the best survival. This view is in keeping with the results of multivariate analyses of prognostic factors in four large series[72–75], two of which each involved over 100 patients[72,73]. These studies stressed the key role of resectional surgery and the unpredictable benefit of additional postoperative treatments.

Any suggestion of potential efficacy of primary chemotherapy with multiple drugs is indirect, coming from studies[50] of patients with stage III or IV disease in whom standard treatment (cyclophosphamide, vincristine and prednisone with or without bleomycin and/or procarbazine) achieved a complete response in 16 of 18 patients and a negative histological result in 90 per cent of those who underwent restaging. In the recent experience of Maor *et al.*[30] with 34 patients classified as stage IE or IIE given chemotherapy (CHOP plus bleomycin) alternated with radiotherapy (a mean of 3946 cGy), the 5-year survival rate was 73 per cent, the disease-free survival rate was 62 per cent, treatment-related deaths accounted for 6 per cent, and 15 per cent of patients experienced serious treatment-related morbidity. The natural history of gastric lymphoma, in which the common pattern of disease recurrence after surgery (with or without radiotherapy) involves distant sites[38,73], suggests that there is a need to include chemotherapy in all treatment protocols.

Surgical resection: how much?

'Local' radicality, i.e. the achievement of tumour-free margins at transection of the stomach, should be distinguished from 'regional' radicality, which means removal of regional lymph nodes and involved surrounding structures. Although some authors[23,76] have claimed a need for tumour-free resection margins, others have shown by univariate and multivariate analysis that patients whose surgical specimens had margins involved by tumour did not have a worse relapse-free survival than those with clear margins, provided radiotherapy was subsequently given[18,33]. Most authors[26,32,62,66] support the view that subtotal gastrectomy is the preferred procedure when feasible, even though lymphoma is multifocal in 14 per cent of cases[77]. Resection of the whole stomach adversely affects nutritional status and quality of life compared with subtotal gastrectomy[78]. Furthermore, deterioration in nutritional status may lead to poor compliance with further aggressive chemotherapy and so be associated with a poor outcome[79].

The importance of regional radicality in extragastric tissues has been stressed in many multivariate analyses[27,37,43,67,81,82], but the retrospective nature of such studies makes it uncertain whether the poor prognosis after non-radical resection indicates inadequate excision or simply reflects a more advanced stage of disease.

Conclusion

The first reported gastrectomy for lymphoma was performed 76 years ago in a 9-year-old child who was still disease-free 31 years later[44]. Nevertheless, the role of surgery in the treatment of gastric lymphoma is still debated. Whereas there is no doubt that surgery may be recommended when there is a strong suspicion of lymphoma but histological confirmation is lacking or in emergency conditions due to gastric bleeding or perforation, the necessity and timing of elective gastrectomy in patients with an established diagnosis and stage IE or IIE gastric lymphoma are controversial. For a proper comparison between surgery and chemotherapy or radiotherapy, not only oncological results but also morbidity and mortality rates resulting from therapy should be analysed.

The operative mortality rate for elective subtotal or total gastrectomy was about 3 per cent in the present authors' series[62] and <5 per cent in a survey of the literature[63] on patients operated on in the decade 1980–1990. Total gastrectomy is accompanied by nutritional sequelae[78] that may be clinically significant, particularly in elderly patients. However, such patients are also poor candidates for chemotherapy or radiotherapy.

In recent chemotherapy protocols[83–87], the rate of treatment-related death for nodal non-Hodgkin's lymphoma ranged from 1 to 10 per cent, depending on the aggressiveness of the regimen. Furthermore, there is evidence that acute non-lymphocytic leukaemia can occur as a dose-dependent treatment complication[88–91], as can carcinoma of the urinary bladder[92] and (more sporadically) Hodgkin's disease[93].

We maintain that elective gastrectomy, preferably subtotal, is required in patients with stage I gastric lymphoma. The oncological results of surgery alone are good and treatment-related mortality is limited. Adjuvant treatments have no proven value but, if deemed desirable, they may be administered safely without the related risks of iatrogenic bleeding and perforation. However, it is questionable whether it is possible to identify patients successfully at this initial stage.

With progressive advances in technology and expertise, endoscopists have recently succeeded in detecting 'early lymphoma' as a lymphoma limited in its depth of infiltration to the mucosa and submucosa[94–96]. It is noteworthy that the incidence of early gastric lymphoma among non-Hodgkin's lymphomas of the stomach ranges from 21·7 per cent in German-speaking countries[37] before 1988, to 47·9 per cent in the recent experience of Stolte and Eidt[80], to 45·9 per cent[97] in the Japanese literature. Moreover, such studies found a correlation between limited infiltration of the lymphoma and both a low degree of malignancy[80,98,99] and a low rate of involvement of perigastric lymph nodes[80,97]. The advent of endoscopic ultrasonography[69,71] also seems to have promise for accurate preoperative staging of the disease. Adequate preoperative staging of the lymphoma should therefore enable the oncologist to define the prognostic factors (stage IE, size <7 cm, no involvement of the serosa) that determine a successful outcome following surgery alone[32].

For patients with stage IIE disease, some authors[22,26,52] advocate primary chemotherapy with or without radiotherapy, which could be followed by gastrectomy in non-responders. Although this approach, which has not yet been validated by controlled studies, is interesting, it should be realized that surgery in patients receiving chemotherapy or radiotherapy carries an operative risk higher than that in untreated patients.

Finally, the present mortality rate after elective subtotal or total gastrectomy is 2–3 per cent in European studies, including the present authors' own[106], but it may increase fivefold to tenfold in an emergency setting. Balancing the risk of early surgery against surgery following medical therapy implies maintaining the prevalence of iatrogenic haemorrhage or rupture at a rate of 0·2–0·6 per cent, a value much lower than that reported in the literature.

It is imperative that future cooperative studies aimed at determining the optimal therapeutic approach should consider, besides stage of disease, other traditional and new prognostic indicators, such as nodular pattern and low nuclear grade *versus* diffuse and high-grade patterns[39,100,107], and levels of Ki67, a nuclear marker of tumour proliferation[108]. This will be possible only if patients are enrolled in prospective multicentre protocols.

Mr A. MacDonald, Department of Surgery, Ayr Hospital, Ayr KA6 6DX, UK

Until recently, the surgical management of idiopathic slow-transit constipation had remained unchanged since the condition was first described by Arbuthnot Lane in 1908. Although colectomy and ileorectal anastomosis is a successful treatment for the majority of patients, symptoms persist or are worse in some cases following such surgery. The previously inaccessible colon is now an area of interest in both health and disease; recent observations on aetiology, clinical investigation, neuropathology and surgical outcome lead us to question the rationale of colectomy for all patients with severe constipation.

At the beginning of this century Arbuthnot Lane[1–4] reported in a series of communications to the *British Medical Journal* the results of colectomy and ileorectal anastomosis for severe constipation. He identified a group of patients, predominantly women of child-bearing age or younger, with severe constipation whose symptoms could be improved dramatically by removal of the colon. He also observed that the colon of these women, although macroscopically normal, was non-functional. The syndrome became known as Arbuthnot Lane's disease. In the absence of a pathognomonic test we will never know whether the disease he treated (with some success) is the same as that which we now call idiopathic slow-transit constipation (ISTC). Equally, in the absence of histology that identifies a pathological abnormality, we do not know whether the condition that we treat 80 years on, with no greater a success rate, is Arbuthnot Lane's disease[5,6].

ISTC is currently defined as a disorder of normal colon propulsion that results in severe constipation. By convention, the condition excludes megarectum and megacolon.

Pathophysiology

Constipation is a common clinical complaint, but what the patient means by the term is often unclear[7]. Normal bowel function is difficult to define, but most people defaecate between three times a day and once every 3 days[8,9]. Marginal infrequency beyond this may be attributed to poor diet and frequently responds to bulk laxatives[10]. Many other constipated patients who do not respond to bulking agents find that symptoms improve with cisapride[11]. Clinicians are increasingly recognizing a group of patients with severe chronic constipation whose symptoms are not helped by bulking agents, prokinetic drugs or other laxative therapy. These patients, who are invariably women, defaecate as infrequently as once every 3–4 weeks and seldom without the aid of an enema or anorectal digitation. On taking a detailed history, two groups of patients may be distinguished. First, there are those whose symptoms date from their adolescence or earlier and whose condition has progressively deteriorated with time[12–14]. In contrast, women in the second group attribute the onset of the condition to a recognizable event, such as pelvic surgery or childbirth. Women in the first group are defined physiologically as having delayed colonic transit[15–17], i.e. ISTC, and those in the second by an inability to expel a balloon from the rectum, implying a rectal–pelvic floor dysynergia[18–21], i.e. outlet obstruction constipation. The picture is confused by the observation that some patients with evidence of ISTC also appear to have features of outlet obstruction constipation[22,23]. Patients with delayed colonic transit with or without outlet obstruction should be classed as having ISTC, while those with outlet obstruction constipation alone should not be included in this nosological category.

Patients who suffer from ISTC often complain of urological symptoms. Urodynamic studies demonstrate detrusor dysfunction, indicating that an abnormality of the autonomic nervous supply to the bladder may be present[24,25]. Further investigations have shown that denervation in the bladder often coexists with rectal denervation[26], consistent with Cannon's law of denervation hypersensitivity[27,28]. In contrast, studies performed in patients who attribute their symptoms to childbirth suggest that there is resulting obstructed urinary flow that cannot be accounted for on the basis of autonomic neuropathy[29]. This might be explained by primary damage to the pelvic floor during a traumatic second stage in childbirth, resulting in dysynergia of rectal and urethral emptying mechanisms.

The pelvic floor and its nerve supply are at risk during prolonged labour and in some cases even normal childbirth is associated with a permanent change in pelvic floor anatomy and physiology[30]. The recent observation[31] that a denervation injury can result following hysterectomy lends some support to the hypothesis that trauma can result in disordered rectal physiology. More recent studies in an animal model have demonstrated that afferent input emanating from one pelvic organ may reflexly inhibit motility in another[32]. The bladder, vagina, uterus and rectum appear to be physiologically linked, and surgery to one structure may alter afferent or efferent function in an adjacent organ. However, patients with constipation after hysterectomy appear to be clinically indistinguishable from those in whom the condition arises *de novo*[33]. In addition, other workers have shown that urological symptoms attributed to hysterectomy are often present before surgery, but are given heightened significance afterwards[34]. The same may be true of constipation.

The source and distribution of both the sympathetic and parasympathetic supply to the left colon and rectum are now more clearly understood. Injury to the autonomic supply to the pelvis and rectosigmoid may occur during pelvic surgery[35,36]. Experimental work has shown that, following such injury, subsequent imbalance of reinnervation with proportionally more sympathetic nerve fibres may contribute to dysfunction[37,38]. It has been shown in patients that resection of the rectosigmoid may interrupt the pelvic nerves in their course through the left colon[39,40], and rectal surgery is often associated with the development of constipation[41].

The aetiology of outlet obstruction constipation is often apparent; patients attribute the onset of symptoms to

0007-1323/93/091107-05 © 1993 Butterworth-Heinemann Ltd

hysterectomy or childbirth. However, it is more difficult to explain logically the aetiology of slow-transit constipation that coexists with pelvic floor dysynergia.

Childhood constipation is not sex specific and yet those presenting with ISTC are almost exclusively female. It is tempting to 'blame it on the hormones', with the onset of menstruation acquiring particular significance. Progesterone in pharmacological doses has been shown[42,43] to relax both animal and human colonic smooth muscle *in vitro*. Similarly, the *in vitro* responsiveness of ileum and colon to acetylcholine is reduced in the presence of progesterone[44]. A similar picture has been demonstrated in the smooth muscle of the gallbladder and at the gastro-oesophageal junction, which implies that progesterone may have an inhibitory effect on the whole gastrointestinal tract[45]. Although some women do suffer from constipation during pregnancy, the precise aetiology is unclear. Abnormally high concentrations of the sex hormones have been detected in the urine of women with severe constipation, but this may be related to abnormal enterohepatic circulation and may not be the primary cause. Sex hormones appear to have little effect on the colonic motility of non-pregnant healthy women, as colonic transit is unaffected by the menstrual cycle[46]. However, a role for the sex hormones in severe constipation has not been established.

Routine light microscopy usually fails to identify a persistent abnormality in the severely constipated colon. The first reported histological abnormality was by Dyer and colleagues[47] in 1969. This comprised thickening of the circular smooth muscle, a reduction in the number of axons and neurones, which were often misshapen, and Schwann cell hyperplasia. In a recent study Krishnamurthy *et al.*[48] noted changes in the myenteric plexus of patients with idiopathic constipation that appeared to be distinct from other pseudo-obstruction syndromes[49-52]. Confirming the previous observation of Dyer *et al.*, they noted a reduction in the total number of argyrophilic neurones, coupled with a morphological abnormality. The total number of axons was also decreased and there was variability in the size and chromatin content of the nuclei. However, they did not report the circular muscle hyperplasia and Schwann cell hyperplasia previously identified by Dyer *et al.*[47]. The findings of Krishnamurthy and co-workers were distinct from previous reports of patients with megacolon, which identified pathology in hypertrophy of the smooth muscle layer[53]. A third study of four adults with organic constipation supported these findings: Smith and colleagues[54] reported a quantitative decrease in the number of argyrophilic neurones but no Schwann cell hyperplasia.

The advent of special stains has now opened the door for the re-exploration of the morphology of the severely constipated colon. The absence of an extrinsic nerve supply in the colon of some patients with long-standing constipation is an exciting discovery[55]. Furthermore, Koch *et al.*[56] showed that the levels of vasoactive intestinal peptide (VIP) and peptide histidine–methionine were reduced in a small series of patients with severe constipation. In addition, they demonstrated that VIP-containing nerves were absent from the circular smooth muscle. This observation has been supported recently in a study by Milner *et al.*[57], who reported reduced levels of VIP in the sigmoid colon of patients with ISTC. As VIP is thought to be a non-adrenergic non-cholinergic inhibitory transmitter intrinsic to the production of the peristaltic wave, its absence could point to the primary pathology in ISTC. Other evidence exists for a functional cholinergic deficit in patients with severe constipation[58].

The extent of the pathology has not been clearly established. The proximal gastrointestinal tract has not been adequately studied in ISTC, but some series have reported oesophageal dysmotility in a proportion of patients[48]. This suggests that, in some patients at least, ISTC may represent the most prominent feature of a pangastrointestinal tract disorder. Considering the multiple aetiologies of this condition, there may be a variety of pathologies and unravelling the neuropathology remains a considerable challenge.

Diagnosis

In screening patients with constipation, radiological marker studies and videoproctography form the basis of investigation. Many patients thought to suffer from ISTC have the diagnosis excluded following normal transit studies. Significant delay in colonic transit can be identified using the technique originally described by Hinton *et al.*[59]. The presence of 80 per cent of radiological markers in the left colon 5 days after ingestion suggests the diagnosis, and their persistence on days 7 and 10 confirms it. A modification of this technique, involving taking three different markers on consecutive days, enables measurement of segmental transit[60]. This modification may be helpful in identifying right- and left-sided colonic delay[61].

Videoproctography is now preferred to balloon proctography by some clinicians for diagnosing outlet obstruction constipation following the observation that normal control subjects sometimes have difficulty expelling a balloon from the rectum. Although failure to open the anorectal angle is of debatable significance, inability to evacuate the rectum of liquid barium is a reliable indicator of pelvic floor dysynergia. Electromyography is used by some clinicians to examine the external anal sphincter and contractility of the puborectalis. Whereas changes in electrical activity have been demonstrated in the sphincter mechanism during simulated defaecation, the same changes have also been reported in normal volunteers. This might be explained by the presence of subclinical disease in some of the controls. Alternatively, it is perhaps expecting too much of asymptomatic people to behave in a physiological manner with needles in the perineum. More importantly, the results of electromyography do not always correlate with those of manometry or videoproctography, or indeed symptoms, and so the value of any of these measurements in isolation is questionable[62].

Colonic motility may be further examined in ISTC by use of colonic manometry. The passage of a nasal catheter into the right colon or a rectal catheter into the left colon has been used for research purposes[63-65]. Such studies suggest that dysmotility may be either total or regional, due to hypersegmentation as opposed to hyposegmentation, or to infrequent or absent mass movements. Potentially useful information from colonic manometry is undermined by the infrequent nature of events and by the fact that segmental colonic contraction may not cause a rise in intraluminal pressure, the pressure being dissipated by adjacent segmental relaxation. Similarly, the abnormally high pressure recordings that are sometimes detected in the sigmoid colon may be due to kinking of water-perfusion catheters as they descend into the pelvis. Likewise, high pressures in a particular region of the bowel may result from recording through a side channel as opposed to an end port, the first being more likely to record wall pressure and the second true intraluminal pressure. Thus, care is needed to determine the significance that should be placed on the magnitude of pressure rise in any particular area of the colon. Perhaps it is more important to note qualitative differences, such as whether pressure waves are present or not and whether they represent prograde or retrograde movement[66].

Whichever way the colon contracts, one of its roles is to transport colonic contents from the caecum to the rectum, and much might be learned from observation of this task. The imprecise and infrequent nature of events makes continuous monitoring difficult. However, in a well designed study of a small number of patients, Kamm *et al.*[67] artificially reduced the period of colonic transit by stimulating the caecum with bisacodyl and observing with a γ camera the subsequent passage of a radionuclide tracer through the colon. They demonstrated that some patients with severe constipation had motility patterns in the right colon and transverse colon that were comparable to those of normal controls, with abnormal patterns confined to the distal colon or rectum. Other patients appeared to have an abnormal motility pattern in the whole colon. The former observation might support the results of other studies[31] that have implicated pelvic denervation as the cause of left-sided constipation. It is interesting to speculate that the latter observation may reflect the situation in pure ISTC.

Treatment

Surgery for severe constipation has been loosely based on a concept of the pathology. Colectomy and ileorectal anastomosis has remained the treatment of choice for ISTC in preference to other surgical options such as limited resection[5]. A satisfactory outcome is achieved in the majority of patients, but a small number are still unable to defaecate after ileorectal anastomosis[5,6,68]. The reason for this is unclear but in some patients there is spasticity of the rectum with pseudo-obstruction of the distal ileal segment. For this reason some authors[69] have recently used proctocolectomy and ileoanal pouch formation for ISTC. Such an approach is not without problems, such as urgency, faecal incontinence and recurrent obstruction, which may eventually result in a permanent ileostomy. The delivery of fluid stool to the rectum may overwhelm the outlet obstruction, as it is intended to do, but, if the sphincter mechanism has been damaged by repeated straining, surgery may succeed only in converting a chronically constipated patient into a faecally incontinent one. It is therefore vital to be able to measure sphincter function before surgery. Where the dysmotility is segmental rather than total, removal of the colon may represent surgical overkill. Recent reports have suggested that left hemicolectomy and excision of the upper rectum can be successfully employed where dysmotility is confined to the distal large bowel[70].

Where outlet obstruction constipation occurs in combination with slow transit, surgery is directed towards the colon and the pelvic floor is ignored. However, where the primary pathology was thought to have its origin in the pelvic floor, surgery has been directed towards the local problem. Previous attempts to deal with outlet obstruction by division of the puborectalis muscle have met with mixed results. The rationale for doing this is to decrease the pressure in the anal canal during defaecation. In practice, incontinence of flatus and mucus have occurred too frequently for the operation to have increased in favour[71–73]. Similarly, the poor long-term results of anorectal myectomy do not justify its 10 per cent incontinence rate, and this operation has been abandoned[74]. Attempts to treat outlet obstruction constipation with locally acting neurotoxin have also been unsuccessful in the long term[75]. The presence of a strong psychological overlay in many patients has prompted some workers to treat this component using biofeedback techniques, with some success[74]. Anismus in these cases is considered to be a learned response, possibly secondary to painful defaecation. Contraction of the external sphincter during defaecation persists, despite the cause being removed. As only the striated muscle is involved, this should be amenable to modulation by biofeedback[76]. Although initially labour intensive, early results are promising and sustained improvement has been reported[77–79]. However, the ability to pass a rectal balloon is not dependent on the coordinated function of the puborectalis and external sphincter alone[78]. Biofeedback may be of benefit in the group of patients who are unable to empty a loaded rectum, but results are poor in ISTC in which the problem is not how to empty the rectum but that the rectum is often empty.

Future prospects

At present, the investigation and management of ISTC is based on a thorough history, videoproctography and transit studies (either total colonic or segmental). However, some patients fail to benefit from surgical treatment and it is important to establish whether they suffer from dysmotility of the more proximal gastrointestinal tract. The authors' clinical impression accords with the findings of others, that some patients with ISTC have proximal disease affecting to a varying extent the oesophagus, stomach and small bowel[48]. These patients might not benefit from colectomy and ileorectal anastomosis, as the proximal dysmotility may form the major component of their disease. Measurement of gastric emptying and small bowel transit will identify such patients, in whom more observation is needed to determine the natural history of the disorder.

Some patients fail to evacuate following ileorectal anastomosis; contrast studies have shown that the rectum fails to admit ileal contents and is spastic in appearance, the adjoining ileum becoming markedly dilated[5]. These patients might be identified by a combination of anorectal manometry and neostigmine–carbachol sensitivity testing. The presence of rectal hypersensitivity might persuade the surgeon to remove the rectum in addition to the colon, leaving the patient with an ileal pouch.

The advent of total colonic manometry might help to elucidate the regional nature of ISTC, if indeed there is one. The technology is now available to measure colonic motility over a 24-h period. Responses to stimuli, both natural and pharmacological, can be measured on a regional basis, and the localization of areas of dysmotility may offer the possibility of a more precise and limited resection. It is perhaps time to evaluate all the various investigations in relation to each other and to establish the best management protocol. We may still find ourselves depending on a clinical history, transit studies and videoproctography, but the exercise is worth pursuing. In addition, neuroendocrine histology must be painstakingly performed on all resected specimens and the results correlated with presentation, investigation and outcome.

To remove the colon in severe constipation is a surgical option but it has little scientific basis. Failure to define clearly the nature and extent of the pathophysiology will result in the condition continuing to be known as Arbuthnot Lane's disease. While this is unimportant for the majority of patients for whom we get it right (like Arbuthnot Lane), it is very important for the smaller number for whom we get it wrong.

Editors' announcement

Case Reports

It is the policy of the Editorial Board of the Journal to limit strictly the number of Case Reports that appear in each issue. During recent months we have been inundated with Case Reports; consequently there has been a very high rejection rate. We remain interested in receiving Case Reports of particular novelty or rarity, but brevity is another criterion of increasing importance. Contributors should note that a succinct Case Report can be used to fill a page that would otherwise be largely empty. To meet this requirement, it has proved necessary to tighten the existing guidelines for Case Reports. From now on they should be no more than 400 words in length or no more than 300 words if a figure is included. The existing limit of five references remains. We strongly encourage contributors to observe these new guidelines so as to avoid automatic rejection of their Case Reports.

For this quarter's digest Professor Christian Herfarth and Dr Thomas Lehnert have selected from the April to June issues of Der Chirurg. *The best of the* BJS *for the same period appears in the German journal this month.*

Laparoscopic surgery

Cholecystectomy

The past months' issues of *Der Chirurg* carried a total of 14 contributions in the field of laparoscopic procedures. To determine the current status of surgery for gallstones in Germany a group from Munich[1] sent out questionnaires containing 28 questions to 449 surgeons. A total of 188 complete returns were evaluable and contained information covering 17 232 hospital beds with 405 668 operations performed in 1991. Some 27 403 of these operations (7 per cent) were performed for gallstone disease and 84 per cent represented simple cholecystectomy without exploration of the common bile duct (CBD). In all, 43 per cent of surgeons claimed to have had previous experience with laparoscopic cholecystectomy, 28 per cent started the technique during the observation period and 11 per cent indicated that they would soon start laparoscopic cholecystectomy. It was estimated that in 1993 more than 90 per cent of surgeons will have experience with laparoscopic cholecystectomy. Between 50 and 60 per cent of surgeons would not consider laparoscopic cholecystectomy for patients with cholecystitis, coagulation disorders, choledocholithiasis or previous abdominal operations. Only 6054 of the reported operations (25 per cent) were performed laparoscopically, with a conversion rate to open cholecystectomy of 6·8 per cent. Causes for conversion were adhesions, bleeding and technical problems. Injury to the CBD was recorded in 36 instances. Overall, 98 per cent of surgeons considered preoperative ultrasonography mandatory for the open and laparoscopic procedures. Preoperative intravenous cholangiography was considered necessary by only 11 per cent of surgeons for open cholecystectomy whereas 51 per cent considered this procedure necessary before laparoscopic cholecystectomy. In patients with isolated CBD stones (e.g. after cholecystectomy) most surgeons (61 per cent) favoured endoscopic retrograde cholangiography (ERC) plus endoscopic papillotomy. Intraoperative cholangiography was routinely performed by 80 per cent of surgeons during open surgery, but by only 2 per cent during the laparoscopic operation. If patients present with a combination of cholecystolithiasis and CBD stones most surgeons (44 per cent) performed open cholecystectomy and exploration of the bile ducts. Only 7 per cent would remove the gallbladder laparoscopically and resort to postoperative ERC plus papillotomy. Rates of postoperative complications were similar for open (8·7 per cent) and laparoscopic (6·8 per cent) cholecystectomy, although slightly more patients required relaparotomy after the laparoscopic procedure (1·5 *versus* 0·8 per cent). The mortality rate was 0·14 per cent after laparoscopic and 0·43 per cent after open cholecystectomy.

A similar retrospective survey[2] was performed in Austria in 1991. The questionnaire contained only 17 questions and was honoured by a 100 per cent return rate. Of 13 763 cholecystectomies performed in 1991, 7351 (53 per cent) were undertaken laparoscopically. The conversion rate to open operation was 2·1 per cent mostly because of bleeding or injury to the CBD. Findings from the Austrian study were similar to those of the German survey in that 99 per cent of surgeons required preoperative ultrasonography. Again, 80 per cent of patients scheduled for laparoscopic cholecystectomy underwent intravenous cholangiography. Relaparotomy after laparoscopy was required in 66 patients (0·9 per cent) and the mortality rate after laparoscopic cholecystectomy was 0·05 per cent (four patients). The mean hospital stay was 4·5 days and only a few procedures were carried out on an outpatient basis.

A large survey from Switzerland[3] recorded data prospectively from members of the Swiss Working Group on Laparoscopic and Thoracoscopic Surgery. A total of 3722 laparoscopic cholecystectomies were performed in the 50 member institutions between November 1989 and February 1992. Some 1268 open cholecystectomies were carried out during the same period in these departments. All patients had preoperative ultrasonography and 82 per cent were examined by intravenous cholangiography. The conversion rate to open cholecystectomy was similar to that of the German retrospective experience at 7 per cent. Postoperative complications were noted in 87 patients (2·3 per cent) and 39 (1·0 per cent) required relaparotomy within 30 days, the most frequent indication being injury to the bile ducts or leakage. Three patients died after operation, giving a mortality rate of 0·08 per cent.

A group from Munich[4] provide a comprehensive review of the literature on open and laparoscopic cholecystectomy published between 1986 and 1992, and conducted a postal survey by sending a questionnaire to 22 German centres experienced with the laparoscopic procedure, collecting data on approximately 13 000 patients treated between 1990 and 1992. For open cholecystectomy ($n = 18017$) the authors calculated a complication rate of 5·8 per cent and mortality rate of 0·5 per cent. The respective figures for laparoscopic cholecystectomy ($n = 25644$) were 4·4 and 0·09 per cent. In the collected series from 22 centres with a special interest in the laparoscopic method the complication rate was 5·3 per cent and the mortality rate 0·1 per cent. The authors stress that proper patient selection and care to avoid bile duct injury are mandatory to maintain good results from laparoscopic techniques. Injury to the CBD was often recognized late and they suggest that any deviation from a smooth postoperative course should prompt immediate investigation.

Herniorrhaphy

Laparoscopy has also been applied for inguinal hernia repair. Papers from Austria, Switzerland, France and Germany[5–8] describe prosthetic mesh reinforcement of the inguinal region. A group from Vienna[5] give technical details of the open technique of preperitoneal mesh reinforcement. A large mesh is used to reinforce the symptomatic and contralateral sides, even if there is no clinical evidence of herniation at the latter. Polyester mesh is preferred over polypropylene since its texture allows it to remain in place without additional suturing. Although predominantly employed for recurrent hernia the technique was used for primary hernia with good short-term results.

A paper from Aarau, Switzerland, reports results of a prospective study of open mesh repair for recurrent inguinal hernia[6]. Using a similar preperitoneal approach in 47 patients with recurrent hernia the authors recorded no postoperative infection. One patient required drainage of wound seroma. All patients were followed for a median of 20 (range 12–60)

0007-1323/93/091112-03 © 1993 Butterworth-Heinemann Ltd

months. Only one patient had another recurrence at 6 months, which was successfully repaired using an anterior approach.

The same preperitoneal mesh repair was performed laparoscopically by a French group[7] in 93 patients with 110 inguinal hernias. These authors used a polypropylene mesh, which was stapled in place using a three-cannula technique. With growing experience the average time for the procedure now is 30 min.

Experience with laparoscopic preperitoneal mesh repair in 59 German patients was also reported[8]. There was a 25 per cent recurrence rate when an absorbable mesh prosthesis was used in the first 16 patients. Using a polypropylene mesh with extensive fixation (ten to 14 staples), no further recurrences have occurred to date in 57 operations. No deep infection of the prosthetic material was recorded although one patient had infection of the trocar site.

Opponents of mesh repair techniques consider infection of the graft material and hernia recurrence the two major potential problems. Although long-term recurrence rates for the new methods cannot yet be documented, the low perioperative infection rates are encouraging; late infection may, however, become apparent only after several years.

Fundoplication

DeMeester and Peters[9] reviewed the current indications for gastro-oesophageal antireflux procedures and noted that good results depend on proper patient selection. Patients with normal peristalsis of the lower oesophagus were treated by a 360° Nissen fundoplication performed laparoscopically. For those with compromised peristalsis or aperistalsis the authors recommend an open Belsey procedure using a transthoracic approach. Patients with brachyoesophagus are not deemed candidates for the laparoscopic operation and in those with acid hypersecretion addition of a vagotomy is suggested. The review of criteria for patient selection is followed by a well illustrated step-by-step description of laparoscopic Nissen fundoplication.

Deep vein thrombosis

Low-dose heparin prophylaxis is standard treatment for hospital patients in the postoperative period. In ambulatory medicine no clear treatment policy has been established for patients requiring prolonged immobilization of fractured extremities but who do not require hospitalization. A group from Essen[10] in 1991 embarked on a randomized controlled trial to answer two questions: (1) What is the incidence of deep vein thrombosis (DVT) in ambulatory patients with immobilization of the lower extremity for 'minor' injury?; and (2) Can low molecular weight heparin (LMWH) prophylaxis reduce the incidence of thrombosis in these patients? Prospective candidates for the trial were studied by duplex ultrasonography and a number of other tests to exclude pre-existing DVT before randomization to heparin or no treatment. Treatment consisted of a daily subcutaneous dose (0·3 ml) of LMWH equivalent to 1500 aPTT units and 3000 anti-Xa units. Most patients were instructed in self-injection. The first dose of heparin was administered on the day the cast was applied and the last given on the day it was removed. Sex distribution, average age, height and Broca index were comparable for the two groups. Potential risk factors for the development of DVT such as smoking, obesity, presence of varicose veins and contraceptive use were comparable in both groups. During the study period 306 patients were considered eligible for the trial. Twenty-seven patients were excluded, because of risk factors precluding heparin treatment. Thirty-eight randomized patients were not evaluable, because they were operated on at a later stage ($n = 14$), did not attend the final examination ($n = 21$) or switched treatment groups ($n = 3$). A total of 241 evaluable patients thus completed the study (treatment group, 115; control group, 126). The total time of immobilization was 15 days in patients given heparin compared with 18 days in those not so treated. No patient in the treatment group was found to have developed DVT compared with five of 126 (4·0 per cent) controls ($P = 0{\cdot}04$). No correlation could be established between the duration of immobilization and the incidence of DVT, with three of five instances of thrombosis diagnosed in the first week of immobilization. No severe side-effects of heparin treatment were recorded. The authors conclude that one daily self-application of LMWH is safe and effective in preventing DVT in outpatients requiring plaster immobilization of the lower extremity.

Soft tissue sarcoma

The June issue carries the first part of a series of leading articles on soft tissue sarcoma. Murray Brennan[11] reviews the vast experience of the Memorial Hospital, New York, with soft tissue sarcoma in 2044 patients treated between 1982 and 1992. Multivariate analysis determined tumour grade, deep location and size >5 cm as independent prognostic factors of survival and development of metastases. Management strategies focus on multimodal therapy. An ongoing prospective randomized study of adjuvant brachytherapy has demonstrated reduction of local recurrence rate in high-grade tumours, although long-term survival was not significantly improved. It also emerged from the data that small ($\leqslant 5$ cm diameter) soft tissue sarcoma of the extremities has a favourable 5-year survival rate of 94 per cent irrespective of tumour grade, depth, location or type of surgical treatment and should, therefore, not be included in future randomized trials studying adjuvant treatment.

A paper from the University of California at Los Angeles[12] reports preliminary results of a prospective study of adjuvant preoperative and postoperative radiochemotherapy for high-grade soft tissue sarcoma. Between 1989 and 1992, 42 patients with tumours of various location and histological origin were recruited. Radiochemotherapy consisted of two 6-day courses of ifosfamide (14 g/m^2) and a third 2-day course of cisplatin (120 mg/m^2) plus doxorubicin (60 mg/m^2). In addition, patients received radiotherapy with 40–50 Gy (T-18 protocol). After surgical removal of the tumour the course of chemotherapy was repeated. All patients completed the preoperative treatment course and 31 of 42 completed the postoperative chemotherapy. At a median follow-up of 2 years no patient had developed local recurrence. Three patients died during follow-up, giving an overall survival rate of 93 per cent, while the recurrence-free survival rate was 86 per cent.

It would seem that progress is being made and the second part of this series on soft tissue sarcoma to be published in the July issue of *Der Chirurg* is anticipated.

The American Journal of Surgery

The April to June issues of The American Journal of Surgery *form the basis for this quarter's digest prepared by that journal's Editor, Dr Hiram C. Polk Jr. A summary of the same months'* BJS *by our own Professor John Farndon appears in the September issue of the American journal.*

Br. J. Surg. 1993, Vol. 80, September, 1114–1115

Laparoscopic cholecystectomy

The April issue[1] consists of papers presented at the Consensus Conference arranged by the National Institutes of Health in Bethesda, Maryland, on 14–16 September 1992, attempting to put laparoscopic cholecystectomy into perspective. It addresses issues of the pathogenesis of gallstones, the non-operative care of patients and the combined use of laparoscopic and endoscopic techniques, and draws a reasonably careful set of conclusions regarding the role of these less invasive procedures for biliary tract disease in 1993. The NIH Consensus Conferences have evolved over the past decade as an important mechanism for bringing mainstream medical and scientific thought to the public's attention. The even-handedness and breadth of material in the special issue is impressive.

Pancreatic cancer

The role of the Whipple operation has been a subject of surgical thought for many years. The critical issue in managing cancer of the head of the pancreas is in establishing its resectability and lack of involvement of vital structures such as the superior mesenteric vein. Papers from the Virginia Mason Clinic, under the leadership of Traverso, have often focused on such issues. A report from the North Pacific Surgical Association describes the relative value of contrast-enhanced computed tomography (CT) *versus* angiography and clinical observation at surgery[2]. CT detected vascular invasion that had been overlooked on angiography in 20 per cent of patients and angiography detected invasion indicating inoperability in 5 per cent. There were other CT criteria of irresectability in this 5 per cent of patients and angiography provided no supplemental staging information. The authors conclude that CT accurately predicted irresectability in every patient and that resectable tumours were identified in 72 per cent of cases.

The same group examined visceral angiography as an aid to intraoperative surgical decision making in a similar group of patients[3] and concluded that 30 per cent of 64 angiograms showed a significant vascular abnormality requiring specific preoperative or intraoperative measures. This particular group recommends the advantages of contrast-enhanced CT as an initial screen for resectability and suggests that angiography is helpful in selected patients to guide the operative strategy.

Portal hypertension

The imagination of the interventional radiologist has led to the transjugular intrahepatic portacaval shunt to provide portal decompression without operation. The University of Washington faculty at Seattle describe experience in which 93 per cent of 59 consecutive patients ultimately received successful shunting although one-third required more than one procedure[4]. The 25 per cent hospital mortality rate was not related to Child's grade but to the presence of haemorrhage at the time of the attempted shunt procedure. Some 12 per cent of patients developed early occlusion of the intrahepatic shunt. The place of the procedure alongside sclerotherapy and conventional surgery, which preserve hepatopedal blood flow, remains to be defined.

Dialysis

Erythropoietin has been a broadly used agent to treat the anaemia intrinsic to chronic renal failure. Examining shunts used for chronic haemodialysis, the Portland group showed that suspicions of an increased rate of thrombosis of dialysis grafts are unfounded[5]. This verifies the absence of a serious side-effect of erythropoietin but does not address its cost-effectiveness.

Complications of biliary procedures

The relative role of endoscopic retrograde cholangiopancreatography (ERCP) with laparoscopic cholecystectomy in the treatment of operative complications is not defined. There is a

0007-1323/93/091114-02 © 1993 Butterworth-Heinemann Ltd

growing incidence of acalculous cholecystitis in patients treated laparoscopically, a number that may have increased more than fivefold compared with that of the open operation. The group at the Virginia Mason Clinic in Seattle describe experience with ERCP after laparoscopic cholecystectomy[6]. This was an effective technique for dealing with several injuries, including those to the bile duct that required stenting and papillotomy. They concluded that surgery could be avoided in a large number of patients.

Ress *et al.*[7] from the Mayo Clinic provide their first report on the early management of major injuries occurring during laparoscopic cholecystectomy. Approximately half the patients were treated by definitive bile duct reconstruction. The emphasis on long-term and definitive repair was clear.

Soper *et al.*[8] at Washington University describe a similar number of patients with biliary complications incidental to laparoscopic cholecystectomy. The majority of patients were treated by combined radiological, endoscopic and operative therapy. They identified the most common error in the initial operation to be mistaking the common bile duct for the cystic duct, and stressed the importance of a multidisciplinary approach to the patient who is suspected of having sustained such an injury.

The combination of the laparoscopic surgeon with someone skilled in ERCP has brought skills to bear on a group of patients who were traditionally at very high risk for conventional surgery. There is a small incidence of duodenal perforation associated with ampullary papillotomy. Chung *et al.*[9] at the Cleveland Clinic describe a clinical scenario and suggest that prompt improvement in symptoms within the first 24 h is associated with spontaneous recovery. Operation was recommended when: (1) pain or abdominal signs were prominent; (2) there were signs of intraperitoneal infection; or (3) there was failure to respond to a short trial of non-operative care.

Wound healing

The variety of nomenclature and actions of wound healing factors is complex and challenging. Bennett and Schultz[10] from the University of Florida provide a two-part summary of wound healing as modified by epidermal growth factor, transforming growth factor β, platelet-derived growth factor, insulin-like growth factor and fibroblast growth factor families. This paper is a resource document for those trying to understand wound care and the potential clinical application of these substances. The randomized prospective clinical trial may clarify such issues, although whether one can study wound healing in a 'blinded' study of topical agents remains to be seen. Contemporary reports are filled with small series and/or inadequate controls that trumpet the value of many new treatment protocols. This paper defines in an effective way the range and current potential role of these materials.

Digest

SURGERY TODAY
The Japanese Journal of Surgery

Br. J. Surg. 1993, Vol. 80,
September, 1116–1117

Professor Yoshio Mishima has this month selected from the April, May and June issues for his digest from Surgery Today (The Japanese Journal of Surgery).

Oncology

Oka *et al.*[1] investigated the immune function of peripheral blood cells and cells from the pleural and abdominal effusions of patients with advanced cancer. This was compared with function of peripheral blood cells from controls. The parameters examined included lymphocyte subsets, natural killer (NK) cell activity, and anti-DAUDI and lymphokine-activated killer (LAK) cell activity. The percentage of CD4$^+$ pleural and peritoneal exudate cells was significantly higher than that of peripheral blood mononuclear cells (PBMCs) in patients. The proportion of CD8$^+$CD11$^+$ pleural and peritoneal exudate cells and PBMCs (suppressor T cells) of patients was increased compared with controls. The percentage of CD8$^+$CD11$^-$ pleural and peritoneal exudate cells (cytotoxic T cells) was identical to that of the PBMCs of patients and controls. The NK cell activity of pleural and peritoneal exudate cells was significantly lower than that of PBMCs in both patients and controls, and there was no correlation between the NK cell activity of PBMCs and pleural and peritoneal exudate cells. Although the anti-DAUDI activity of pleural and peritoneal exudate cells was markedly low, LAK cells with high activity could be induced by culture with interleukin (IL) 2 for 4 days. These results suggest that the immune function of cells in malignant effusions may be depressed because of a low population of cytotoxic T cells, low NK cell activity and increased suppressor T cells, while the local administration of IL-2 may induce LAK cells. Effective local immunotherapy for malignant effusions should augment effector cells and inhibit suppressor cells.

COL-2-JCK, a human colonic cancer xenograft line that can be transplanted into nude mice, was implanted in the subserosal layer of the caecum, either as tumour tissue or as a single cell suspension. When cancer tissue was used for the caecal implantation, 100 per cent extensive local tumour growth and a high incidence of metastasis to the regional lymph nodes, peritoneum, liver and lung were observed. In contrast, when the COL-2-JCK cell suspension was injected into the caecal wall, no metastases were observed, with significantly reduced local tumour growth. Experimental studies should maintain the original tumour tissue structure to allow full expression of the biological characteristics of the cancer phenotype. According to Furukawa *et al.*[2] this nude mouse model of caecal implantation might allow better understanding of the biology of human colonic cancer.

Transplantation

Ohzato *et al.*[3] evaluated sequential serum IL-6 levels in the diagnosis of hepatic allograft rejection. This study was conducted in nine cynomologous monkeys that had undergone orthotopic hepatic allotransplantation, six of which were treated with FK-506 (a new immunosuppressant agent isolated from *Streptomyces tsukubaensis*) and three of which were not. The untreated animals showed biochemical abnormalities from days 5 to 6, characterized by a marked increase in serum alkaline phosphatase levels. These animals died on days 8, 12 and 63 (group I). Acute cellular rejection was confirmed by histological study of the hepatic grafts taken at autopsy or biopsy. Four of the treated animals (group IIa) survived more than 30 days and had a slight increase in alkaline phosphatase level (<2000 units/l). Histological examination at 30 days after transplantation revealed a transient infiltration of polynuclear cells into Glisson's area, with the portal vein and bile duct remaining intact. The remaining two animals (group IIb) died from dehydration and arterial thrombosis on days 5 and 7. A kinetic study of serum IL-6 conducted during the first 2 weeks showed quite different patterns among the three groups. All recipients in group I demonstrated two peaks following grafting, on days 1 and 3 or 4, the second peak of above 2·0 units/ml preceding biochemical abnormalities by 2–3 days. Conversely, the recipients in group IIa showed a single peak of serum IL-6 on day 1, followed by a decrease to less than 2·0 units/ml. Group IIb characteristically showed a high level of serum IL-6 on day 1, after which the value remained above 2·0 units/ml. The monitoring of serum IL-6 proved useful for detecting the acute rejection of hepatic allografts, the recipients with rejected grafts displaying two peaks of the interleukin. The first rise was observed on day 1, which might reflect the stress of the surgical procedure. The second transient increment was seen on day 3 or 4 and might suggest acute hepatic rejection, preceding biochemical abnormalities by 2–3 days.

Gastric cancer

The long-term effects of gastrectomy on nutritional and immunological status were investigated by Tsuburaya *et al.*[4]. The study was prospective in 79 patients with gastric cancer who underwent curative gastrectomy and were followed after operation for an average of 5 years 3 months. The proportion of actual body-weight to normal weight before illness was less than 95 per cent in 80 per cent of the study patients. Levels of retinol-binding protein, prealbumin and albumin were lower than normal in 17, 26 and 26 per cent of patients respectively. The mean values of the percentage of normal weight, and levels of retinol-binding protein and prealbumin were significantly lower in those undergoing total than in those undergoing subtotal gastrectomy (P < 0·01). The method of reconstruction did not affect the nutritional status except for the prealbumin level, which was significantly lower in patients with Roux-en-Y procedures than in those with interposed segments after total gastrectomy. Cell-mediated immunological alterations after gastrectomy were observed in 31, 37 and 71 per cent of all patients for the OKT3 subpopulation, OKT4:OKT8 ratio and blastogenesis by phytohaemagglutinin respectively. Multivariate analysis revealed that the long-term immunity of patients after gastrectomy was not affected by the levels of albumin and rapid-turnover proteins but by splenectomy and weight loss.

Intestine

To determine the absolute minimum tissue blood flow for safe colonic anastomosis, the wound healing of anastomotic sites with varying degrees of blood flow (measured by laser Doppler fluxmetry) was examined in dogs by Kashiwagi[5]. The correlation between the flux value and tissue blood flow measured by the hydrogen gas clearance method was good (r = 0·91). After transection and anastomosis of the colon with varying degrees of devascularization, anastomotic wound healing was examined. The laser flux values at the anastomotic sites of all dogs in which dehiscence had occurred were less

0007-1323/93/091116-02 © 1993 Butterworth-Heinemann Ltd

than 0·8. In the groups receiving 2 and 4 cm of devascularization, the mean(s.d.) flux values were 1·23(0·34) and 0·88(0·20) respectively. There were significant differences between the latter two groups concerning postoperative course, histological features and hydroxyproline concentration. If the laser Doppler flux value at the anastomotic site is at least 1·0, corresponding to about 30 per cent of the tissue blood flow of the intact colonic wall, the anastomosis is considered to be safe and without risk of dehiscence.

Biliary tract

Bile duct neoplasms occur relatively often in Taiwan in patients with hepatolithiasis. Ker *et al.*[6] studied 49 patients with positive immunoperoxidase staining for carcinoembryonic antigen (CEA) in the bile duct glands in relation to the concentration of CEA in serum and bile. The mean(s.d.) bile concentrations of CEA in 15 control patients, 16 patients with hepatolithiasis, seven with hepatolithiasis and bile duct carcinoma, and 11 with bile duct carcinoma only were 4·09(4·12), 70·49(81·62), 137·73(66·15) and 144·3(117·31) ng/ml respectively. A positive CEA stain from the bile duct was seen in 13, 81, 86 and 91 per cent of each group respectively. No strongly positive stain (grade 2 or 3) was found in the control group but was seen frequently in patients with hepatolithiasis and bile duct carcinoma. This study suggests that there is likely to be an associated neoplasm in patients with hepatolithiasis if the CEA level in the serum or bile is raised.

Breast

Fukutomi *et al.*[7] investigated the relationships between residual cancer and age, tumour location, tumour diameter, mammographic findings, presence of nipple discharge, histopathological type, lymphatic and/or vascular invasion by tumour cells, histological grade, histological lymph node metastases, and oestrogen receptor (ER) status in 1494 patients with breast cancer that involved diagnostic excisional biopsy. Residual cancers were found in 581 of 1448 mastectomy specimens (40 per cent), after 46 (3 per cent) with multicentricity had been excluded. No correlation was observed between residual cancer and age, histological grade or ER status. However, residual cancer rates were significantly higher in patients with tumour diameters $\geqslant$3·1 cm, tumours beneath or in the vicinity of the nipple–areola, malignant calcifications noted on mammography, serous or bloody nipple discharge (particularly with positive cytological findings), papillotubular carcinoma diagnosed by biopsy, lymphatic invasion by tumour cells or a high number (four or more) of lymph node metastases. These seven clinicopathological factors are thus considered useful prognostic indicators for local recurrence in breast conservation therapy with lumpectomy.

Cardiovascular surgery

Aoyagi *et al.*[8] studied 11 patients undergoing replacement of the aortic arch or adjacent areas for aneurysmal disease between 1989 and 1991, using hypothermic cardiopulmonary bypass at 20–23°C with partial brachiocephalic perfusion. Selective perfusion of the innominate artery was performed in all 11 patients through the right axillary artery, while partial brachiocephalic perfusion was carried out using a separate arterial roller pump with a flow rate of 10 ml per kg per min. Direct cannulation to the left common carotid and left subclavian arteries was not performed. There were four men and seven women who ranged in age from 26 to 78 (mean 56) years. The aetiology of aneurysmal disease was aortic dissection in ten patients and aortitis in one. The mean(s.d.) cardiopulmonary bypass time was 214·3(39·3) min, aortic cross-clamping time 131·5(33·4) min and partial brachiocephalic perfusion time 57·6(15·1) min. There were three operative deaths, from multiple organ failure, acute peritonitis and infection of the composite graft in the ascending aorta in one patient each. There were no deaths related to the technique of partial brachiocephalic perfusion and no neurological complications. Partial brachiocephalic perfusion under hypothermic cardiopulmonary bypass is proposed as a safe and effective technique in surgery for aneurysm involving the aortic arch.

Paediatric surgery

It is well documented that piriform sinus fistulas often cause suppurative thyroiditis. The diagnosis is difficult when suppurative thyroiditis does not occur. Hashizume *et al.*[9] describe 11 patients with piriform sinus fistula. A conventional surgical approach was performed in the first eight patients and there were four recurrences in two. A new technique was introduced for the next three patients and for one with recurrence. The internal orifice of the fistula was viewed with a laryngoscope, after which a transverse incision on the neck was made and the abscess dissected. The side wall of the piriform sinus was then opened with the help of a laryngoscope, and the bottom part of the mucosa of the sinus transected with the internal orifice of the fistula. The fistula was then removed *en bloc* with the bottom part of the sinus and abscess cavity. Using this technique no complications occurred and there have been no recurrences so far.

Approximately 12 per cent of limbs undergoing intra-arterial thrombolysis (IAT) develop distal embolism or extension of thrombus during the procedure. These are usually of little clinical consequence and can be treated by increasing the rate of administration of the lytic agent. However, in some patients the clinical condition of the limb deteriorates rapidly. In an attempt to define the incidence of acute limb deterioration during IAT, information was collected from five centres in the UK with experience of the technique. A total of 866 treatments were recorded, with 20 limbs (2·3 per cent) undergoing acute deterioration. This complication was more common during the treatment of thrombosed popliteal aneurysm than during that of emboli or thrombosed atheromatous arteries or grafts ($P < 0.001$)*. The amputation rate associated with the complication was high, and operative intervention provided better results than continuation of lysis.*

Few surgeons in the UK have a large experience of intra-arterial thrombolysis (IAT)[1,2]. The technique does, however, provide a valuable means of clearing blocked grafts[3], native arteries occluded by embolus or thrombus[4] and thrombosed popliteal aneurysms[5]. Factors influencing success include duration[2] and length[4] of the occlusion, and the state of the run-off[6]. The main complications of the procedure are stroke, occurring in approximately 1 per cent of cases, and major haemorrhage, occurring in 5 per cent. Minor haemorrhage and catheter-related problems have been described in approximately 15 per cent of treatments[7].

Recently, a further major complication of IAT has been highlighted: acute catastrophic deterioration of the limb during treatment. This often occurs at a time when lysis appears to be progressing satisfactorily[8]. This paper describes the combined experience of this type of problem from five centres in the UK; an attempt has been made to define patients at particular risk.

Patients and methods

During September 1992 information was collected from the five participating centres (Reading, Bristol, Nottingham, Guildford, London), all of which had a wide experience of IAT. The number of episodes of thrombolysis, the type of occlusion treated and the number of cases of acute limb deterioration were noted. Some degree of limb deterioration often takes place during lysis. For this study, only limbs that suddenly became non-viable during lysis were included, and a record was made of the treatment and outcome of the complication. Each of the centres recorded data prospectively; details of the techniques used in the different centres are well documented[2,6,9–11].

Results

Table 1 shows the total number of patients in the combined series and the number having acute limb deterioration during lysis. No significant difference emerged between the results of the five centres. The incidence of deterioration due to ischaemia was higher in patients undergoing thrombolysis for thrombosed popliteal aneurysm than in those having treatment of thrombosed atheromatous arteries or grafts ($\chi^2 = 24{\cdot}8$, 1 d.f., $P < 0{\cdot}001$). The median time of onset of acute deterioration from the start of lysis was 9 (range 4–48) h.

Of the 20 patients whose limb deteriorated during treatment, 18 initially presented with rest pain, one with rest pain and gangrene, and one with incapacitating claudication. All but two patients presented within 1 month of the onset of symptoms, 11 within 1 week and six within 24 h. The lytic agent was streptokinase in nine cases, recombinant tissue-type plasminogen activator (rtPA) in ten and acetylated plasminogen–streptokinase activator complex in one. No particular type of catheter was noted to be associated with development of the complication.

Table 2 shows the management and outcome in 19 cases. A further patient who had complete clearance of run-off after thrombosis of a popliteal aneurysm is excluded. This patient's limb deteriorated suddenly towards the end of infusion, despite the angiographic appearance remaining satisfactory. The man developed renal failure as a result of rhabdomyolysis from a compartment syndrome, ultimately dying after fasciotomy and subsequent amputation.

Continuation of lysis with a higher dose of agent resulted in the salvage of two limbs; five were lost and two of these

Table 1 *Incidence of acute deterioration of limbs due to ischaemia during intra-arterial thrombolysis*

	No. treated	No. with acute deterioration
Native artery	710	11 (1·5)
Graft	110	3 (2·7)
Popliteal aneurysm	46	6 (13)
Total	866	20 (2·3)

Values in parentheses are percentages

Table 2 *Management and outcome after acute limb deterioration due to ischaemia in 19 patients*

Outcome	Continued lysis ($n = 7$)	Operative intervention* ($n = 12$)
Limb salvaged	2	6
Amputation	5	6
Death	2†	0

*Includes one percutaneous transluminal balloon angioplasty. †The two who died were among the five who underwent amputation

0007-1323/93/091118-03 © 1993 Butterworth-Heinemann Ltd

patients died. Operation resulted in the salvage of six of 12 limbs with no deaths. No angiograms were taken after deterioration of the limb in the 12 operated patients. However, in the seven patients who were treated by continued lysis, the angiographic findings after the complication occurred included complete occlusion of the calf vessels (two patients), and fresh embolus into the tibioperoneal trunk (four) and calf vessels (one).

Discussion

In this series 2·3 per cent of 866 patients experienced sudden catastrophic deterioration of the limb during IAT. Those with a thrombosed popliteal aneurysm seem to be at particular risk; 13 per cent developed the complication.

Acute limb deterioration during IAT needs to be differentiated from rethrombosis after successful lysis. The latter is not uncommon and has been described in 96 of 386 successfully cleared lesions in one series[4]; it occurs particularly during the first few weeks after completion of lysis. Occlusive problems occurring during IAT are also well described and include pericatheter thrombosis, progression of thrombus and the production of emboli. The review of published papers in *Table 3* suggests that distal embolism occurs four times more commonly than thrombosis. However, pericatheter thrombosis has been described in up to 26 per cent of cases by some[25].

Hess *et al.*[4] subdivided emboli into two types. Microemboli produced transient ischaemia in 46 (7·2 per cent) of 637 treatments. Macroembolism occurred in 43 (6·8 per cent) but was associated with deterioration of the limb in only one case. Embolism or thrombosis occurring during IAT generally requires no treatment other than increasing the rate of infusion of the lytic agent and perhaps positioning the catheter more distally. Fragmentation of the clot to produce emboli is a complication of the lytic process that has been described with both IAT and intravenous thrombolysis[26]. On the other hand, thrombosis may be a risk that is specific to the presence of the perfusing catheter within an artery. Infusing heparin with the lytic agent in an attempt to prevent pericatheter thrombosis has sometimes proved successful[27], but concern has been expressed that a combination of the two drugs may lead to an increased incidence of haemorrhagic complications.

Approximately 12 per cent of patients experience embolism or extension of thrombosis during lysis, but it is apparent that this is associated with no or only transient clinical deterioration in most cases. The present data suggest that about 2 per cent of patients will experience acute limb deterioration, although this will vary depending on case mix. Increasing the rate of lysis is satisfactory for treating asymptomatic or minimally symptomatic occlusions, but appears less satisfactory in the presence of marked symptoms. It was found that rates of both limb salvage and survival were higher in patients treated surgically than in those receiving continued lysis.

Massive distal embolism from thrombus destabilization is probably the commonest cause of this problem, although there may be others. Compartment syndrome after successful IAT requiring fasciotomy is also well documented[17] and acute deterioration may represent a reperfusion syndrome. A further potential problem is blockage of important collateral vessels by the perfusing catheter.

Table 3 *Review of published papers describing 1306 treatments using intra-arterial thrombolysis*[4,12–24]

Complication	No. of patients ($n = 1306$)
Distal embolism	134 (10·3)
Thrombosis	32 (2·5)
Total	166 (12·7)

Values in parentheses are percentages

In conclusion, acute catastrophic limb deterioration occurring during apparently successful thrombolysis is a very real problem of which vascular surgeons and radiologists need to be aware. Despite the higher incidence of the complication in patients undergoing lysis for thrombosed popliteal aneurysm, we still feel that IAT has a role in this condition. The aim of IAT is to clear run-off before ligating the aneurysm and we recommend that, rather than placing the infusing catheter in the superficial femoral artery above the aneurysm, it should (if possible) be passed through the latter so that the calf vessels can be infused directly. An alternative is to infuse either streptokinase or tPA into the calf vessels during the operation after ligating the aneurysm. Early results using this technique are encouraging[28].

Paper accepted 22 January 1993

Announcement

The Vascular Surgical Society of Great Britain and Ireland

The Annual General Meeting of the VSS this year will be held at the Royal Northern College of Music in Manchester on 18 and 19 November. Following receipt of a generous offer of sponsorship by The British Journal of Surgery Society, Council has decided that two separate prizes will be awarded for papers presented at the AGM.

The British Journal of Surgery Prize will be awarded for the best paper presented by a surgeon in training on basic or laboratory-based vascular research. The Founder's Prize will be awarded for the best paper presented by a surgeon in training on clinical research. The value of each prize is £500.

Further information about eligibility and instructions for entering will be circulated with the abstract and registration documents for the meeting.

Sources of air embolization during carotid surgery: the role of transcranial Doppler ultrasonography

M. E. Gaunt, A. R. Naylor, R. D. Sayers, D. A. Ratliff and P. R. F. Bell

Department of Surgery, Leicester Royal Infirmary, PO Box 65, Leicester LE2 6LX, UK
Correspondence to: Mr A. R. Naylor

Transcranial Doppler ultrasonography (TCD) has shown that air embolization is relatively common during carotid surgery[1,2] and this may be associated with neurological complications[3]. This report describes three unusual but preventable sources of presumed air embolization, one of which may have caused a minor neurological deficit.

Case reports

Patient 1

A 58-year-old man presented with transient ischaemic attacks (TIAs) in the carotid territory caused by 80 per cent carotid artery stenosis and subclavian steal from subclavian artery origin occlusion. He underwent combined left carotid endarterectomy and left carotid–subclavian bypass. The two carotid procedures were completed first, and carotid flow was restored without ultrasonographic evidence of embolization. However, after subsequent restoration of flow to the arm, TCD detected numerous embolic signals in the ipsilateral middle cerebral artery, suggesting that air had reached this artery via the ipsilateral vertebral artery. The patient suffered no neurological sequelae.

Patient 2

A 62-year-old woman underwent left carotid endarterectomy with a Pruitt–Inahara shunt, having presented with TIAs. At 10 min after shunt insertion, TCD detected numerous embolic signals. No obvious source was identified until it became apparent that they were coincidental with the cardiac cycle (*Figure 1*). Closer examination of the operative field revealed that blood was gradually displacing a column of air in the T limb of the shunt. Following removal of all air from the T limb, no further embolic signals were detected. The patient suffered no neurological sequelae.

Patient 3

A 70-year-old man underwent left carotid endarterectomy with a Pruitt–Inahara shunt, having presented with a stroke and residual neurological deficit. As the vein-patch angioplasty was being anastomosed, the distal shunt balloon deflated and was subsequently refilled on two occasions with heparinized saline. Immediately after each inflation, TCD detected numerous embolic signals in the middle cerebral artery and the shunt was removed. This procedure revealed a distal ballon leak (possibly due to a needle stick); a new shunt was inserted and no further embolic signals were detected. After operation the man had a slight worsening of the pre-existing neurological deficit, but this resolved completely within 72 h.

Discussion

Air or microparticulate emboli cause high-energy signals to be superimposed on the middle cerebral artery waveform together with a characteristic high-pitched sound[1,3]. In patient 1, the subclavian artery had obviously not been completely cleared of air before the restoration of flow, and air entered the middle cerebral artery via the vertebral artery. It is recommended that the T limb of the Pruitt–Inahara shunt is cleared of air before use. We can only presume that the shunt was located at a particular angle during the operation that enabled air in the T limb to be progressively displaced by blood. Although a haemodynamic cause for the neurological deficit in patient 3 cannot be excluded, only a few minutes had elapsed before a second shunt was inserted and insertion was not associated with any TCD embolic phenomena. Moreover, because the embolic signals immediately followed balloon insufflation, it can only be assumed that air was inadvertently included in the balloon-inflating syringe and then expelled through the hole.

In each case, embolization could have been avoided. This experience highlights the benefits of TCD in improving operative technique, particularly as one patient may have suffered neurological complication, albeit minor, as a consequence.

Abdominal aortic aneurysm in the elderly

R. T. A. Chalmers, P. A. Stonebridge, T. G. John and J. A. Murie

Vascular Surgery Unit, The Royal Infirmary, Edinburgh EH3 9YW, UK
Correspondence to:
Mr J. A. Murie

Thirty-five patients over the age of 80 years underwent surgery for abdominal aortic aneurysm between January 1985 and December 1990. Of these, 25 had surgery for ruptured aneurysm (mortality rate 56 per cent) and ten had surgery for symptomatic or asymptomatic aneurysm (mortality rate zero). The mortality rate for patients with rupture aged over 80 years was considerably greater than that for those under 80 years of age (56 versus *36 per cent). The mortality rate in the elderly population was zero for elective surgery but in those under 80 years it was 5 per cent. During the study period a prospective analysis of all referrals with aortic aneurysm was carried out, whether or not they underwent surgery and whether or not they were admitted to hospital. The ratio of patients accepted for operation to those not accepted for operation was 92:59 (1·56:1) in the under 80-year-old age group and 12:34 (0·35:1) in those aged over 80 years.*

There is an increasing number of elderly people in the population and an increasing incidence both of abdominal aortic aneurysm (AAA)[1,2] and the number of patients with aneurysm coming to the attention of the medical profession[3]. The decision whether or not to operate on an elderly person with an aneurysm therefore confronts the vascular surgeon more frequently. Several authors have stated that physiological, rather than chronological, age should be a major factor in the selection of patients for aortic surgery[4–8]. The report of the Confidential Enquiry into Perioperative Deaths[9] of 1987, however, suggested that patients over 80 years old with ruptured aortic aneurysm were unlikely to survive surgery and should not be operated on. The present study reviewed the experience of surgery for aortic aneurysm in the elderly in Edinburgh. The Edinburgh vascular surgical service carries out virtually all operations for ruptured aneurysm in the Lothian, Borders and the southern half of Fife Regions (a population of 1·2 million) and is therefore in a position to assess numbers of patients having surgery, and numbers being referred and being refused operation.

Patients and methods

Every patient over the age of 80 years who had undergone surgery for AAA between January 1985 and December 1990 was identified using the Lothian Surgical Audit database. Age at operation, sex, relevant past medical history, operative details, whether the surgery was for ruptured, symptomatic or asymptomatic aneurysm, intraoperative death and its cause, number of days spent in the intensive care unit, length of hospital stay and postoperative death were noted. Survival after discharge from hospital was obtained and an estimate of quality of life made by ascertaining the degree of independence and mobility.

To put the operative experience into context, a prospective study of all patients presenting to the vascular surgical service with an aneurysm (emergency or elective) but turned down for operation in the calendar year 1989 was carried out. This study included patients admitted to hospital who did not undergo surgery and all those notified to the vascular service by hospitals or general practitioners who were discussed by telephone and not transferred or who died during transfer.

Results

In the 6-year period studied, 35 of the 546 aneurysm operations carried out were in patients aged 80 years or over. There were 25 men and ten women with a median age of 81·5 (range 80–85) years. Ten patients underwent elective surgery for an asymptomatic or symptomatic aneurysm and 25 had immediate surgery for a ruptured aneurysm. All operations were carried out by a consultant vascular surgeon or by a senior registrar with consultant supervision.

All ten patients operated on electively survived surgery; five tube and five bifurcation grafts were inserted. No patient required intensive care management after operation. The median hospital stay was 18 (range 13–29) days. Seven of these patients are still alive, living at home or with relatives, and have reasonable mobility.

Seven of the 25 patients who had a ruptured aneurysm died during surgery, three from myocardial infarction and four from uncontrollable haemorrhage. A further seven died in the 30-day period after operation, three from multisystem failure, three from cerebrovascular accidents and one from myocardial infarction. The total 30-day mortality rate was therefore 56 per cent. In the 18 patients who survived operation, 13 tube grafts and five bifurcation grafts were inserted. The type of graft had no apparent influence on outcome as four of five patients receiving a bifurcation graft survived to discharge. Patients who survived to discharge spent a shorter time in the intensive care unit after operation than those who died (median (range) 2 (1–11) *versus* 4 (2–23) days). The median hospital stay for survivors was 15 (range 13–68) days. Six of the patients with a ruptured aneurysm are still alive. All live at home independently and are mobile; one person requires a walking stick.

As the numbers in both the ruptured and non-ruptured groups are relatively small, only a crude estimate of life expectancy after aneurysm surgery can be made. The median survival time for patients undergoing elective surgery who survived to discharge but subsequently died was 3 years 10 months (range 5 months to 5 years 6 months). For patients with ruptured aneurysm the median survival time was 3 years 8 months (range 3–5 years).

In the calendar year 1989, 104 aneurysm repairs (52 ruptured, 52 non-ruptured) were carried out and 93 patients were either deferred or turned down for operation. Of the latter group, 34 (37 per cent) were more than 80 years old (12 ruptured, 22 non-ruptured). Of those with rupture (mean age 86 years), the reason for being turned down for operation was recorded as age alone in two patients, and age and cardiac or respiratory or neurological status in nine; one patient refused operation. Only two of the 12 patients with aneurysm rupture had been seen previously by a vascular surgeon. Of those without rupture (mean age 83 years), the reason for being turned down for operation was given as age alone in six, age and cardiac status in four, age and neurological status in four,

0007-1323/93/091122-02 © 1993 Butterworth-Heinemann Ltd

cardiac status alone in three, and disseminated or inoperable malignancy in four; one patient refused operation. During the same 1-year period, 12 aneurysms (nine ruptured, three non-ruptured) were surgically repaired in the over 80 years age group. The ratio of patients accepted for surgery to patients not accepted for surgery for those aged under 80 years was 92:59 (1·56:1); for the over 80-year-olds it was 12:34 (0·35:1).

Discussion

The results of the present series compare favourably with those of other authors, although quite a spectrum of outcome exists. Robson *et al.*[8] reported a series of 34 octogenarians undergoing surgery for aortic aneurysm which was categorized as 'emergency' or 'elective', with 20 in the former category and 14 in the latter. However, only 14 of the 'emergency' patients had ruptured aneurysm proven at operation and the operative mortality rate for emergencies of 35 per cent must not be confused with the mortality rate for rupture. The mortality rate for 'elective' cases was zero, as in the present series. Harris *et al.*[5] reported a 30-day mortality rate after operated ruptured aneurysm of 37 per cent in this age group and a mortality rate of 3 per cent for patients undergoing elective repair, but this included an operative mortality rate of 27 per cent for patients with symptomatic aneurysm. Treiman *et al.*[6] reviewed 8 years of operations on octogenarians with aortic aneurysm and found an overall operative mortality rate of 58·8 per cent after rupture and 8·6 per cent after elective surgery.

One feature that the present series has in common with most of the above is the high ratio of ruptured to non-ruptured aneurysms operated on; this is generally the case throughout Scotland[3]. This may occur because general practitioners and physicians do not refer elderly patients with aneurysm for surgical assessment, assuming that advanced age is a contra-indication to surgery[10]. A majority of the elderly patients arriving at hospital with ruptured aortic aneurysm have never been previously diagnosed[11]. This has given rise to calls for national screening programmes, especially in high-risk groups[12–14]. The high ratio of ruptures to non-ruptures, 3:1 in the study year, may also be the product of surgical selection; nine of 31 patients with rupture but only three of 25 without rupture known to the vascular surgical service underwent operation in that year. There is understandably more pressure to operate on an aged patient with a life-threatening ruptured AAA than one with an asymptomatic aneurysm.

Elderly patients, especially those with compromised cardiac function, tolerate blood loss poorly, and advanced age itself has been shown to be associated with postoperative complications and death[15]. In the present series, age and medical factors were the reason for withholding surgery in all but eight of the 34 patients not operated on. What should the policy be for surgical intervention in the patient presenting with a ruptured aneurysm who has already been turned down for elective surgery on medical grounds? Sterpetti *et al.*[16] advised operation on all such patients, accepting that the mortality rate is high. Ruckley[17] argued that the elderly patient with a ruptured aneurysm who arrives at hospital severely shocked or comatose is highly unlikely to survive surgery and should not be operated on. Clearly an agreed policy to suit everyone is not possible, and some selection is desirable if the financial and emotional toll (to patients, relatives, surgeons and nursing staff) is not to be too great. While the elective group may represent a highly selected population, the results show that choosing patients carefully does give a good operative outcome and quality of life after surgery. The opportunity for elective selection should be more frequently available. It is widely accepted for younger age groups that it is desirable to reduce the number of operations performed for ruptured aneurysm. The same should obtain in the elderly, and perhaps all patients with aortic aneurysm should be referred for specialist assessment, regardless of age.

Acknowledgements

The authors thank their colleagues Mr A. McL. Jenkins and Professor C. V. Ruckley for allowing patients to be reported.

The Netherlands

A hazard of regional perfusion for melanoma is incomplete isolation, resulting in leakage of the cytostatic drug into the systemic circulation. Data were analysed retrospectively on 438 melphalan perfusions performed for melanoma of the extremities during the period 1978–1990; continuous isotopic measurement of systemic leakage was carried out. The cumulative systemic leakage after 60 min perfusion was 0·9 per cent (95 per cent confidence interval 0·7–1·1 per cent). Systemic leakage of ≥ 1 per cent was detected in 12·6 per cent of perfusions, ≥ 5 per cent in 6·2 per cent and ≥ 10 per cent in 1·4 per cent. In 2·3 per cent of patients, systemic side-effects in the form of mild transient bone marrow depression occurred. Six variables related to the perfusion technique were assessed by multivariate analysis for their influence on systemic leakage. The level of isolation and diameter of the venous cannula emerged as significant factors. In addition, ligation of the internal iliac vein provided optimal isolation during iliac perfusion.

Regional isolated perfusion, introduced by Creech *et al.*[1] in 1958, is frequently used in the treatment of recurrent melanoma of the extremities[2]. Its main advantage is that a high dose of cytostatic drug (usually melphalan) can be given locoregionally, thereby avoiding systemic side-effects[3]. However, complete isolation of the limb is not always possible because of anatomical variation and for technical reasons; systemic leakage therefore sometimes cannot be prevented. In most perfusion centres, control of systemic leakage is carried out using an isotope technique. In the literature, systemic leakage at the end of melphalan perfusion has been reported to be as high as 30 per cent, producing systemic complications (including bone marrow depression) in 2–17 per cent of patients[4–9]. Recently, biological response modifiers such as recombinant tumour necrosis factor (rTNF) α have become available for high-dose regional administration[10]. Because the pharmacokinetic behaviour of these agents is different from that of melphalan and because their systemic toxicity can be severe, a proper isolation technique is even more crucial. Before embarking on perfusion with such agents, past experience of systemic leakage was evaluated. Particular attention was paid to six variables that might influence leakage.

Patients and methods

A total of 499 perfusions in 431 patients with melanoma were performed in the period 1978–1990. A database containing patient, tumour and treatment characteristics was used to acquire information on perfusions during which control of systemic leakage was carried out. Perfusions were divided into two groups: those resulting in systemic leakage of < 1 per cent and those resulting in leakage of ≥ 1 per cent.

The perfusion technique has been described in detail elsewhere[3]. Melphalan was generally given in a dose of 10 mg per litre of tissue for lower-extremity perfusion and 13 mg/l for upper-limb perfusion[11]. Tissue temperature during perfusion was usually 'controlled' normothermic (37–38°C) or, when performed within the framework of the European Organization for Research and Treatment of Cancer–World Health Organization (WHO) protocol for stage I melanoma, 'mild' hyperthermic (39–40°C). A few patients were perfused experimentally using 'borderline' hyperthermia (41–42°C)[12]. Perfusion was carried out with isolation at the axillary, brachial, iliac or femoropopliteal level. For iliac perfusion the internal iliac vein was routinely ligated, except for patients treated in The Netherlands Cancer Institute where this step was abandoned in 1986. To obtain the proximal (axillary or iliac) isolation level, a pin was inserted into the head of the humerus or iliac crest; an occluding rubber bandage was fixed around the pin and twisted around the root of the extremity. This technique prevented collateral circulation in subcutaneous tissue and muscle. To obtain the distal (brachial or femoropopliteal) isolation level, an inflating tourniquet was used. During limb isolation there was a dynamic balance between two pressure compartments, the systemic vasculature and the isolated circuit. The pressure of the former compartment could be influenced by adjusting the systemic blood pressure, while that of the latter was affected by alterations in extracorporeal flow rate.

Any leakage into the systemic circulation was monitored using a radioactive tracer. A small calibration dose of human serum albumin radiolabelled with ^{99m}Tc or ^{131}I was injected into the systemic circulation and a higher dose of the same isotope into the isolated extremity. Continuous monitoring was performed with a precordial scintillation probe. Systemic leakage was expressed quantitatively as a percentage such that 100 per cent leakage represented homogeneous distribution of the isotope in the body[13]. In this model it was assumed that the volumes of the extracorporeal circuit and the systemic vasculature are in the proportion 1:5. The priming volume of the extracorporeal circuit was about 750 ml and was composed of whole blood diluted with plasma expander to a haematocrit of around 30 per cent. The venous pressure in the isolated limb was monitored in the saphenous vein at the ankle. The perfusion procedure was flow-regulated; in the authors' practice the optimal flow rate is considered to be that which gives the highest possible flow without systemic leakage and with an increase in venous pressure of ≤ 10 cmH$_2$O from that at the start of perfusion. Physiological blood gas values are aimed for and a minimal flow rate of 40 ml per min per litre of perfused tissue has generally been found to be optimal[3].

To obtain the relationship between perfusion technique-related factors and systemic leakage, logistic regression analysis was performed using BMDP software (BMDP Statistical Software, Los Angeles, California, USA). The variables examined were: level of isolation, method of occlusion of collateral circulation (rubber bandage or inflating tourniquet), flow-rate adjustment, mean venous pressure of the isolated limb, mean systemic blood pressure and diameter of the venous cannula. The flow-rate adjustment was the necessary decrease or increase in perfusion flow rate according to venous pressure, systemic leakage or blood gas levels during perfusion. Venous pressure and systemic blood pressure were recorded as the mean of the values measured at 0, 30 and 60 min of perfusion. The diameter of the venous cannula determines the resistance to venous outflow[11]. For isolation at the iliac level, the factor of internal iliac vein ligation was also included in the analysis.

Results

Data were obtained on 438 perfusions carried out in 383 patients comprising 281 women and 102 men of mean age 54 (range 17–83) years. Of these, 124 patients were perfused for primary melanoma and 259 for recurrent melanoma of the

0007-1323/93/091124-03 © 1993 Butterworth-Heinemann Ltd

extremities. The mean isotopically measured cumulative systemic leakage after 60 min perfusion was 0·9 per cent (95 per cent confidence interval 0·7–1·1 per cent). Systemic leakage was <1 per cent in 383 perfusions (87·4 per cent) and $\geqslant 1$ per cent in 55 (12·6 per cent). In the latter group, 27 perfusions (6·2 per cent) led to systemic leakage of $\geqslant 5$ per cent and six (1·4 per cent) of $\geqslant 10$ per cent. At 5–10 min after restoration of normal circulation, there was a mean release of isotope from the isolated extremity to the systemic circulation of 4·2 per cent (95 per cent confidence interval 3·9–4·5 per cent). In ten cases (2·3 per cent), systemic leakage (of $\geqslant 5$ per cent) resulted in a moderate bone marrow depression (grade II according to WHO criteria).

Table 1 shows perfusion variables in relation to systemic leakage. With respect to the level of isolation, brachial perfusions were excluded from the analysis because of their small number (nine). With univariate analysis (step 0 in *Table 2*), level of isolation ($P = 0{\cdot}0001$), diameter of the venous cannula ($P = 0{\cdot}011$) and flow-rate adjustment ($P = 0{\cdot}011$) all appeared to be significantly related to systemic leakage. There was also a highly significant difference in systemic leakage between iliac perfusion with and without internal iliac vein ligation. *Table 1* shows that 29 per cent of patients without ligation had $\geqslant 1$ per cent leakage as opposed to 10 per cent of those with ligation. With multivariate analysis, the level of isolation ($P = 0{\cdot}0003$) and diameter of the venous cannula ($P = 0{\cdot}011$) retained their significant predictive value (*Table 2*).

Discussion

The mean cumulative systemic leakage of <1 per cent and the systemic complication rate, in the form of bone marrow depression, of <3 per cent are lower in the present series than in the literature, where leakage of up to 30 per cent[7,8] and an incidence of bone marrow depression ranging from 2 to 17 per cent[4–8] have been reported. This favourable outcome can probably be attributed to differences in perfusion technique and leakage detection method. With regard to technique, perfusion flow rate is an important factor. On the one hand, a flow rate is required that is sufficiently high to ensure physiological blood gas values in the limb while, on the other hand, it should not reach levels causing raised venous pressure, which may give rise to acute regional toxicity after perfusion[14] and systemic leakage[15]. For these reasons, the association of flow rate adjustment with leakage is not unexpected. Flow rates of about 40 ml per min per litre of perfused tissue, as used in the authors' practice, are probably optimal, although some have recommended higher rates[16]. With regard to the method for detecting leakage, we strongly advocate continuous isotope monitoring in preference to interval systemic blood sample control; the former allows flow rate to be adjusted directly according to systemic leakage[7,8].

Multivariate analysis showed that the level of isolation and diameter of the venous cannula were significant prognostic factors related to systemic leakage. Patients treated at the iliac level without ligation of the internal iliac vein had the highest leakage. The difference in systemic leakage between iliac perfusion with and without ligation of the internal iliac vein has also been highlighted in another study, which even advocated temporary occlusion of the common iliac vein to ensure optimal isolation[17]. However, in that study rather high cumulative leakage rates (using ^{125}I-radiolabelled human serum albumin) were reported after both ligation of the internal iliac vein (28 per cent) and occlusion of the common iliac vein (9 per cent). Temporary occlusion of the common iliac vein seems particularly appropriate in reperfusion, at which ligation of the internal iliac vein is sometimes difficult. With respect to leg perfusion, patients in the present study treated with isolation at the femoropopliteal level had the lowest systemic leakage. This may be because of the reliable compression of the inflating tourniquet used for this level, resulting in occlusion of the collateral circulation in subcutaneous tissue and muscle. The beneficial effect of a large venous cannula diameter can be attributed to a lower venous outflow resistance, lower venous pressure and, consequently, a higher flow rate.

When melphalan is given in a single dose at the start of perfusion, as in the present study, its concentration in the perfusate declines rapidly during the early period of drug circulation; there is a 40–50 per cent decrease[18] in melphalan concentration in the perfusate after 10 min and after 30 min of perfusion almost all the cytostatic agent has accumulated in the tissues. This is in contrast to the pharmacokinetic properties of rTNF-α, which has recently been introduced into perfusion methodology. The concentration of this agent remains constant in the perfusate throughout the 90 min of perfusion[10]. Furthermore, in contrast to melphalan, severe acute side-effects have been caused by far lower percentage systemic leakage of rTNF-α. Systemic peak concentrations of both melphalan and rTNF-α have been observed after perfusion when normal circulation was restored[19]. Also, in the present series the highest proportion of systemic isotope (4·2 per cent) was detected after restoration of the normal circulation. Systemic drug levels may derive from vascular components of the extremity or via release of drug from tissue-binding sites; it is possible that the latter plays a role in rTNF-α perfusion.

Clearly it is important that several issues regarding systemic leakage be considered. First, in perfusion of melphalan, control of systemic leakage is of major importance only during the first 30 min of perfusion, whereas with rTNF-α it is essential throughout the entire perfusion period. Second, after detection of systemic leakage during rTNF-α treatment, one should seriously consider discontinuing perfusion. Third, wash-out should be more thorough after rTNF-α than after melphalan perfusion.

In conclusion, flow- and venous pressure-controlled perfusion can result in a low cumulative systemic leakage as measured isotopically. This method, therefore, seems to be adequate for perfusion using rTNF-α, when potential systemic leakage must be avoided to prevent severe side-effects. To optimize isolation, ligation of the internal iliac vein in iliac perfusion procedures should be considered. In addition, a venous cannula with a large diameter should be used whenever possible.

Posterolateral neck dissection, alone or combined with a modified radical neck dissection, may be an appropriate method of treating occult and clinically manifest nodal metastases of malignant epithelial tumours of the skin of the posterior scalp. The technique and results are described in 21 patients treated between February 1981 and November 1989. Transformation of nodal status from cN_0 to pN_+ was seen in five of 13 patients treated electively, who may benefit from such a procedure. During a mean follow-up of 47 months the disease was controlled locally in all patients. Three patients suffered regional recurrence of whom only one had a nodal recurrence within the region previously operated on. The results of this limited retrospective study confirm the value of posterolateral neck dissection in posterior scalp lesions.

Spread to regional lymph nodes occurs infrequently in patients with malignant epithelial tumours of the skin of the head and neck. These tumours fortunately show a predictable pattern of metastases within the nodal region[1]. Lymph node dissection for anterior scalp and ear lesions should therefore contain the preauricular, parotid and jugulodigastric nodes. Malignant epithelial tumours, such as invasive melanoma or squamous cell carcinoma of the scalp and nape of the neck, posterior to a coronal plane through the outer ear canals usually metastasize through the retroauricular and suboccipital nodes to the spinal accessory and upper part of the internal jugular chains (*Figure 1*). Only by a posterolateral neck dissection can occult and clinically manifest lymph node metastases in this region be adequately removed.

This type of neck dissection consists of comprehensive removal of all lymph node-bearing tissue of the retroauricular and suboccipital region in continuity with the contents of the posterior triangle of the neck and internal jugular chain. The operation is usually performed as an *en bloc* procedure with excision of the primary tumour[2-6].

This paper presents the results of this operation and discusses its rationale.

Patients and methods

Surgical technique

The technique for posterolateral neck dissection has been described previously[6] and is based on the description of Rochlin[2]. The spinal accessory nerve, jugular vein, splenius capitis and sternocleidomastoid muscle are preserved. Depending on the site of the primary lesion the operation is performed unilaterally or bilaterally.

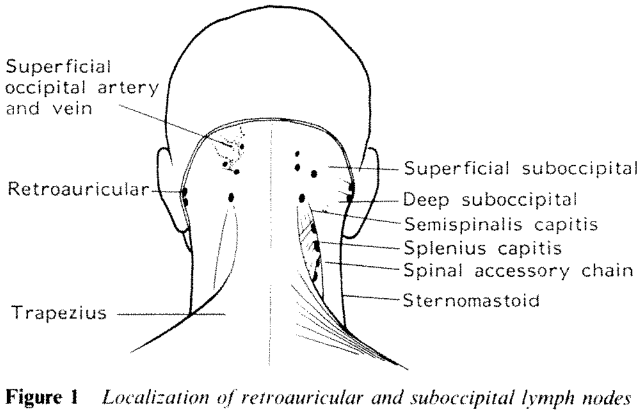

Figure 1 *Localization of retroauricular and suboccipital lymph nodes*

Curved skin incisions are made, extending from a wide local (re)-excision of the primary lesion to the anterior border of the lower part of the sternocleidomastoid muscle. If a concomitant parotidectomy is necessary, as for lesions near or of the ear, a preauricular incision is added with a 90° angle to the vertical part of the incision. Skin flaps are elevated to the midline of the posterior neck to the level of C3-C4, the clavicle and the anterior border of the sternocleidomastoid muscle.

The dissection begins with removal of the fibrofatty tissue and the retroauricular and suboccipital nodes along the occipital artery, which has to be sacrificed. The trapezius muscle is separated from the superior nuchal line up to C3-C4, and the upper portion transected cranial to the entry of the accessory nerve. By retracting the splenius muscle anteriorly it is possible to remove the deep lymph node-bearing tissue in the suboccipital region. The sternocleidomastoid muscle is retracted anteriorly and the dissection carried along the upper portion of the jugular chain including the subdigastric lymph nodes, with preservation of the spinal accessory nerve.

A modified radical neck dissection is carried out when peroperative frozen-section examination of the subdigastric lymph nodes is positive. A split-thickness skin graft is usually necessary to cover the defect at the site of the primary lesion.

Patients

Between February 1981 and November 1989, posterolateral neck dissection was used to treat 21 patients whose clinical characteristics are summarized in *Table 1*. There were 15 men and six women with a mean age of 46 (range 29-69) years. The procedure was therapeutic in eight patients with clinically positive regional lymph nodes. One of these patients had a squamous cell carcinoma of the occipital skin, another a Merkel cell tumour of the pinna and six invasive cutaneous melanoma. An elective operation was performed 'in continuity' in the remaining 13 patients. The criteria for elective regional node dissection were intermediate- and high-risk primary cutaneous melanoma without palpable cervical lymph nodes (stage I, M. D. Anderson Cancer Center classification), with a Breslow thickness $\geq 1 \cdot 0$ mm (seven patients) or any local recurrence or satellitosis within 3 cm of the primary site (stage II) (six patients). The anatomical site of the primary lesions is shown in *Table 1*.

A unilateral procedure was performed in 15 patients, of whom 13 had a primary invasive cutaneous melanoma. Six patients underwent a bilateral procedure as the primary melanoma was located close to the midline of the scalp and neck. All dissections, with the exception of that in the patient with the Merkel cell tumour, were performed in continuity with a wide excision of the primary tumour area. This excision was never <2 cm from the tumour margins or the area of satellite nodules in patients with melanoma. In five patients the procedure had to be extended to a modified radical neck dissection because subdigastric or jugular nodes were positive on frozen-section examination (*Table 2*). In four patients concomitant subtotal parotidectomy was carried out. Owing to the location and extent of the primary melanoma, ear amputation was necessary in two patients.

Local recurrence was defined as any relapse occurring within an area 3 cm from the scar or skin graft. Regional recurrence was divided into nodal and non-nodal relapse, i.e. in-transit or subcutaneous metastases.

0007-1323/93/091127-03 © 1993 Butterworth-Heinemann Ltd

All patients were observed at regular follow-up visits. The median duration of follow-up was 28 (mean 47; range 9–129) months. The evaluation of patients was ended in January 1992.

Results

There was no postoperative mortality and only minimal morbidity (wound infection, one; partial necrosis of the split skin graft, one). The accessory nerve had to be sacrificed for oncological reasons in two patients. In the remaining patients shoulder function was not impaired. In five of the 13 patients who underwent an elective operation after clinical staging (cN$_0$), histological examination revealed positive nodes (pN$_+$). Two of these patients had microscopically involved nodes at various levels, suboccipital and dorsal, without extranodal disease. Resected specimens showed nodal involvement in all of the eight patients who underwent therapeutic dissection. In five of these patients nodal involvement occurred on more levels than was apparent clinically, two with extranodal spread (*Table 2*). There was no local recurrence at the primary site.

Three of the 21 patients suffered regional recurrence. As six bilateral procedures had been carried out, there were 27 neck areas at risk after surgery, and regional failure was recorded in three of the neck regions during follow-up. One of these patients had clinically palpable regional lymph node metastases from a melanoma (stage IIIB); the other two presented with stage I or II melanoma. Only one of these patients had true regional nodal recurrence within the operative area. This patient had undergone elective dissection for a nodular melanoma, 2·8 mm thick, and ulceration. After 13 months he had nodal recurrence in the area previously operated on. Distant metastases were detected 3 years after a subsequent modified neck dissection had been performed. The other two patients developed recurrence outside the previous operative region. Both had synchronous distant metastases. One of these patients developed a subcutaneous recurrence outside the surgically treated field 2 months after a bilateral elective procedure for a primary nodular melanoma with ulceration and Breslow thickness of 5·6 mm. At 1 year he died from distant metastases. A therapeutic dissection was carried out in the other patient for a superficial melanoma, 0·9 mm thick with satellitosis and regional node involvement. At 18 months after this operation lymph node metastasis was observed beyond the dissected field. In the 13 patients (eight therapeutic, five elective) with pathologically proven lymph node metastases, there was only one regional failure.

The mean disease-free survival time for the whole group was 38 (median 24; range 2–129) months, and for patients with a primary cutaneous melanoma it was 31 months. In the elective and therapeutic dissection groups, disease-free survival for patients with melanoma was 36 and 19 months respectively.

The mean survival time of all patients was 47 (median 45; range 9–129) months. In patients with cutaneous melanoma it was 42 months overall, and 46 and 32 months respectively for elective *versus* therapeutic operation.

Seven patients, five with melanoma of the skin, were without evidence of disease, the latter five after a mean follow-up of 56 months (*Table 3*). Of the 11 patients with melanoma and pathologically positive nodes, two are still alive with disease after 78 and 87 months. Ten of these 11 patients had two or more involved nodes.

All patients with stage IIIB melanoma and eight of the 13 without clinically palpable pathological lymph nodes (cN$_0$) developed distant metastases. Three patients with nodes that were found to be negative after dissection developed distant metastases. Regional failure occurred in one patient after 13 months. In patients with pathologically positive nodes, however, regional failure occurred in two patients after a mean of 10 months.

Ten patients died from distant metastases within a median of 23 months. Seven patients had cerebral metastases, six had

pulmonary metastases and two had hepatic metastases. Four patients are still alive with disease after 92, 87, 78 and 45 months.

Discussion

Radical and modified radical neck dissection remains the treatment of choice[7] in the management of cervical metastases at level I through V, but retroauricular and suboccipital lymph node metastases from malignant epithelial tumours of the posterior scalp cannot be removed adequately by standard radical neck dissection[6–9]. In these patients, unilateral or bilateral posterolateral neck dissection should be performed as first described by Rochlin[2], who removed the upper part of the trapezius muscle. Others had a more radical approach with resection of the splenius and sternocleidomastoid muscle for better dissection of the deep suboccipital nodes[2].

Together with the upper back and upper posterior arm, the skin of the nape of the neck and scalp belong to the so-called BANS (back–arm–neck–scalp) region. Due to the rich network of intradermal lymphatics, melanoma originating in the scalp appears to behave more aggressively than that from a non-BANS area[10–12]. Besides a higher frequency of nodular type and ulceration, this detrimental effect on prognosis may also be explained by the fact that these scalp lesions are detected late and at a more advanced stage because of the overlying hair. About 20 per cent of patients with scalp and neck melanoma develop regional lymph node metastases within 2 years and 20–40 per cent of those with head and neck melanoma and clinically negative nodes appear to have microscopic metastases[13–15].

The 5-year survival rate appears to improve when these microscopically positive nodes have been removed electively, and several authors have strongly endorsed wide excision *en bloc* with elective regional node dissection in patients with clinically localized (stages I and II) melanoma[16–19]. Although some multifactorial analyses have shown significant survival benefit in patients with superficial spreading and nodular melanoma, others have detected no survival advantage[20,21]. This controversy will remain in the absence of a prospective randomized study of patients with head and neck melanoma. Adequate removal of microscopic disease seems to be the optimal treatment in patients with primary melanoma[22,23].

This study has shown that accurate preoperative identification of lymph node metastases in this region by palpation alone is insufficient. Five of the 13 patients operated on electively had histologically proven nodal conversion (cN_0 to pN_+). Three of these patients had multiple microscopic nodal foci. Owing to the overlying muscles it is difficult to assess clinically the absence of regional metastatic disease in this area. After posterolateral neck dissection for melanoma of the posterior scalp, regional recurrence occurred in three of the 27 areas at risk, a rate that is in accordance with the literature[24–26]. Only one patient treated unilaterally developed a nodal recurrence within the dissected area. The morbidity of the operation is low and elective dissection is recommended in those with a posterior scalp melanoma $\geqslant 1{\cdot}0$ mm thick or a stage II lesion. This strategy is defensible as therapeutic dissection of pathologically involved nodes in patients with stage II disease is associated with subsequent recurrence in up to 50 per cent of cases[8].

Whether the early detection of clinically occult regional node involvement will lead to an improved survival rate or better locoregional control remains to be proven in randomized studies. In patients without melanoma, posterolateral neck dissection seems to offer an optimal therapeutic effect in combination with postoperative radiotherapy when two or more lymph nodes are positive or in the case of extranodal disease. In patients with invasive cutaneous melanoma the prognosis was adversely affected in those with positive nodes, whether the neck dissection was elective (N_0) or therapeutic (N_+).

A 'TGS' classification for supratentorial brain glioma is proposed, based on three parameters: tumour extension (T), histopathological grade (G) and extent of surgical resection (S). Two groups of patients were analysed: the first ($n = 137$) *had tumour submitted to stereotactic biopsy; the second* ($n = 60$) *had malignant glioma operated on by craniotomy and tumour resection. All three staging parameters significantly influenced survival. Histopathological grade was the most significant factor, and the only independent variable on multivariate analysis, followed by extent of tumour and then extent of surgical resection. The data support the applicability of the proposed parameters for a staging classification of hemispheric brain glioma.*

The staging of malignancy may aid the clinician in planning treatment and making a prognosis, assist in the evaluation of results of treatment and facilitate the exchange of information between centres[1,2]. The tumour node metastasis (TNM) classification is not readily applicable in neuro-oncology. Glioma is mainly a focal disease and over 90 per cent of patients with supratentorial malignant glioma die as a result of recurrence at the original site of the tumour[3,4]. Multicentric lesions account for no more than 6–8 per cent[5,6]; brain tumours usually do not metastasize, the incidence of distant spread of malignant glioma being <10 per cent.

For some tumours, such as soft tissue sarcoma[7], the anatomical extent of the disease is evaluated in association with other tumour characteristics to achieve a clear definition of stage; this may also be possible with brain tumours. Early lesions submitted to a more complete removal and more substantial mass reduction are probably associated with better survival rates. The extent of surgery may be considered an important factor in staging[8]; extent of resection is a useful marker for tumours such as neuroblastoma and nephroblastoma[1,2].

The following parameters were therefore examined as markers for staging supratentorial glioma[9]: T (tumour extent; T_{1-3}), G (grading of anaplasia; G_{1-4}) and S (extent of surgical removal; S_{1-3}) (*Table 1*).

Patients and methods

A total of 197 patients (aged 18–71 years) treated between 1980 and 1988 were analysed. They were divided into two groups. Group 1 ($n = 137$) comprised patients undergoing stereotactic biopsy with multiple specimens collected stepwise at 5–10-mm intervals along the chosen tracks. Different parts of the tumour mass and surrounding brain tissue were analysed. In this group the extent of tumour, inferred from contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI), was confirmed by analysis of specimens taken along the selected trajectories.

Group 2 ($n = 60$) comprised patients with malignant astrocytoma and glioblastoma undergoing surgical resection by craniotomy. After operation patients received conventional external radiotherapy (54–60 Gy in fractionated doses). Tumours in this group had a short natural history and better definition by use of neuroimaging techniques. Tumour extension was assessed by evaluating the maximum diameter of the enhanced area on postcontrast CT scan and, when available, on T1-weighted MRI following gadolinium–diethylenetriamine pentaacetic acid imaging[10]. Tumour grading was evaluated according to the World Health Organization (WHO) classification (1979). The term $G_{2/3}$ was used to indicate astrocytoma demonstrating focal anaplasia (tumour progression)[11], in which it was uncertain whether histological features were grade 2 or 3. The extent of surgical resection of tumour was verified using postoperative contrast-enhanced CT or MRI at 7–10 days and 1 month from operation.

Table 1 *Details of the categories of proposed staging system*

Tumour extent (cm)	
T_1	<3
T_2	3–5
T_3	>5
Grading of malignancy	
G_1	WHO I
G_2	WHO II
G_3	WHO III
G_4	WHO IV
Extent of surgical resection	
S_1	Gross total removal (tumorectomy)
S_2	Subtotal removal (residual disease <10 per cent)
S_3	Partial removal

WHO, World Health Organization

Survival estimates and actuarial curves were determined using Kaplan–Meier and Bergson–Gage methods. Differences between curves were assessed by the log rank test. Pearson's correlation coefficient (r) and the Cox proportional hazards regression model were used in a stepwise manner to determine the relative prognostic significance of the three variables tested (T, G and S).

Results

Details of patients according to TGS status are shown in *Tables 2* and *3*.

Group 1

T. The prognostic influence of tumour extension was evaluated within the most consistent and homogeneous histopathological group, glioblastoma (G_4) (*Figure 1*). The mean(s.e.m.) 1- and 2-year survival rate for T_2 glioblastoma was 17·6(9·2) and 5·9(5·7) per cent respectively, with a median survival time of 9 months. In contrast, the mean(s.e.m.) survival rate at 4 months for T_3 glioblastoma was 16·6(8·8) per cent dropping to zero by 1 year (median survival time 5 months).

G_2	25	1	13	11
G_3	2	0	0	2
Glioblastoma (n = 43)				
G_4	43	0	21	22

G. The influence of grade of malignancy on survival was assessed within the group with the most homogeneous T status, those with T_3 astrocytoma (*Figure 2*). In these tumours the mean(s.e.m.) actuarial survival rate for G_2 astrocytoma at 5 and 9 years was 85·7(13·2) and 57·1(21·7) per cent respectively,

Table 3 *Details of patients undergoing surgery* (n = *60*)

	T_1	T_2	T_3	S_1	S_2	S_3
Anaplastic astrocytoma (G_3; n = 23)	0	14	9	8	12	3
Glioblastoma (G_4; n = 37)	0	20	17	13	17	7

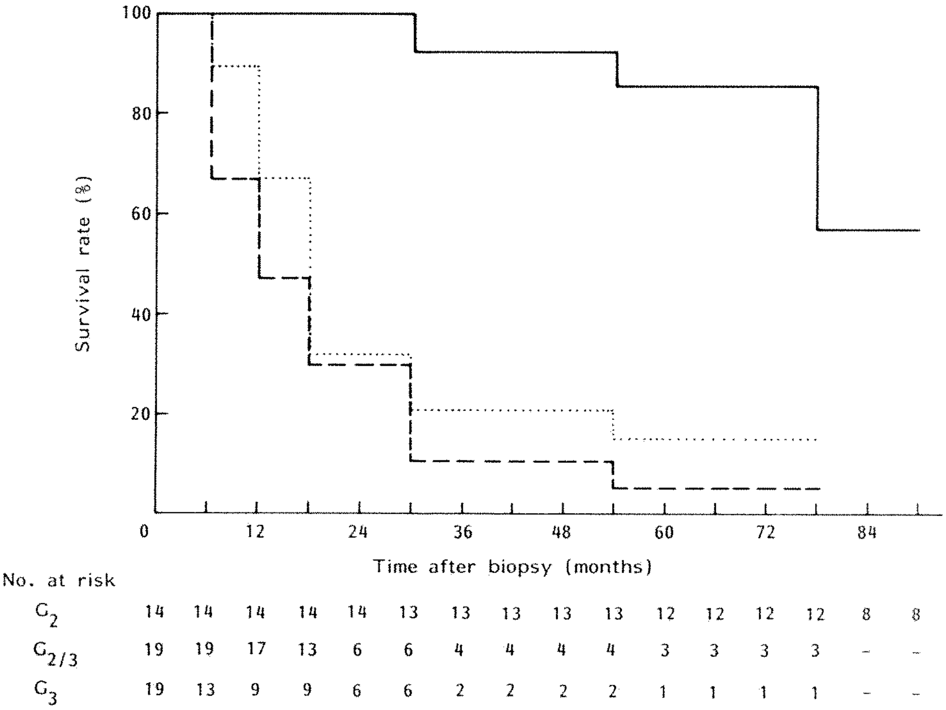

Figure 2 *Survival curves for 52 patients with astrocytoma of tumour extent T_3, according to histological grade of anaplasia.* ——, G_2 (n = *14*); ·····, $G_{2/3}$ (n = *19*); - - -, G_3 (n = *19*). P < *0·003* (*log rank test*)

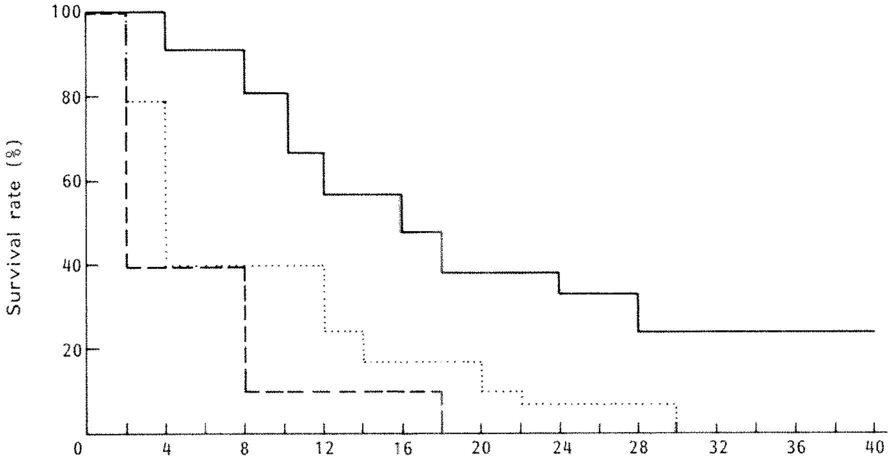

No. at risk																					
S_1	21	21	21	21	20	19	17	14	13	12	10	9	8	8	7	7	5	5	5	5	5
S_2	29	29	27	23	20	17	14	11	7	5	5	5	3	2	1	-	-	-	-	-	
S_3	10	10	8	4	4	4	1	1	1	-	-	-	-	-	-	-	-	-	-	-	-

Figure 3 *Survival curves for 60 patients with malignant glioma, according to extent of surgical resection.* ——, S_1 (n = *21*); ·····, S_2 (n = *29*); – – –, S_3 (n = *10*). P < *0·0002* (*log rank test*)

with a median survival time of 114 months. For G_3 astrocytoma, the mean(s.e.m.) cumulative survival rate at 2 and 5 years was 29·4(11·2) and 5·2(4·7) per cent respectively, with a median survival time of 13 months. The category $G_{2/3}$ showed a survival rate closer to G_3 than did G_2 astrocytoma (median survival time 22 months).

Group 2

S. The influence of the extent of surgical resection on survival was tested in malignant astrocytoma and glioblastoma. *Figure 3* shows survival rates for the whole series with respect to degree of tumour removal. The mean(s.e.m.) 1- and 2-year survival rates after gross total removal (S_1) were 69·1(11·2) and 38·0(10·0) per cent respectively (median survival time 20 months); after subtotal removal (S_2) the values were 38·2(9·2) and 7·0(6·3) per cent respectively (median survival time 12 months). Patients undergoing partial removal (S_3) showed a mean(s.e.m.) 1-year actuarial survival rate of 11·4(12·2) per cent, which dropped to zero at 18 months (median survival time 6 months). The median survival time for malignant astrocytoma alone was: S_1, 74 months; S_2, 16 months; and S_3, 6 months. For glioblastoma the S_1 group had a median survival time of 14 months, S_2 9 months and S_3 5 months.

Multivariate analysis of the whole series of 197 patients showed a hierarchy in the prognostic significance: G was the most influential and the only independent variable ($r = -0·05$ *versus* T, $r = 0·06$ *versus* S; $P = 0·0004$), followed by T ($P = 0·013$) and S ($P = 0·11$). This last parameter correlated with T ($r = 0·65$, $P = 0·01$); cutting off the masking effect of T, so S became significant ($P = 0·003$).

Discussion

Difficulties have been encountered in developing staging systems for tumours of the central nervous system. Attempts have been made to stage infratentorial tumours in children[12,13]. In 1985 Edwards and Klein[14] proposed a series of prognostic factors (TGSM), similar to those in the present paper, to stage hemispheric tumours. The prognostic importance of T, G and S was stressed by Kricheff *et al.*[15] in 1963. In 1987 the Union Internacional Contra la Cancrum[2], drawing on an American Joint Committee on Cancer proposal, suggested a TNM-like classification for brain tumours, utilizing the factors T, G and M. This is the only current system but its faults are[16]: the T parameter includes tumours assessed either by spatial extension (T_1 and T_2) or by location (T_3 and T_4) so that tumours <5 cm in size are not adequately specified; G should refer to the WHO classification of brain tumours and any reference to the amount of anaplasia is anachronistic; and the classification is not equally suitable for all intracranial tumours, some of which (such as meningioma and midline tumours) have peculiar characteristics.

The present paper represents an initial step to describe a staging system for cerebral hemispheric glioma. The following aspects can be outlined.

1. The results confirm the prognostic value of the controversial factor T. There was an ordering of tumour size, such that patients with lesser tumour extension had longer survival. The subdivision proposed was schematic and, in part, arbitrary, but proved to be of practical value and statistically significant.
2. The data confirm the relevance of G and the difficulty in assessing tumour grade in astrocytoma, due mainly to the heterogeneity of such tumours[11].
3. The results confirm the prognostic value of surgery, longer survival being associated with more extensive tumour resection.
4. T and S correlated in the multivariate analysis, as if surgical resection could replace the importance of tumour extension by reducing tumour mass.
5. Even if G is the most significant parameter, S and T heavily influence survival.

It is difficult to know whether this method of staging is suitable for hemispheric glioma. More patients and longer periods of observation are required for validation.

Forty-five patients with Graves' ophthalmopathy were studied prospectively. Twenty-one patients (42 orbits; group 1) were treated surgically by subtotal thyroidectomy and 24 (48 orbits; group 2) received radioiodine therapy. All patients underwent tests of thyroid function, ophthalmological examination, and axial and coronal computed tomography before and 12 months after treatment. Patients in group 1 showed significant improvement in the Feldon score ($P < 0\cdot001$)*, in proptosis as estimated by Hertel exophthalmometry* ($P < 0\cdot001$) *and in proptosis* ($P < 0\cdot001$)*, maximum diameter of the medial rectus* ($P < 0\cdot01$)*, lateral rectus* ($P < 0\cdot05$)*, superior group* ($P < 0\cdot05$) *and inferior rectus* ($P < 0\cdot001$) *muscles as estimated by computed tomography. Patients in group 2 showed significant improvement only in the Feldon score* ($P < 0\cdot05$)*. The ophthalmopathy of Graves' disease improves to a greater extent after subtotal thyroidectomy than after radioiodine therapy.*

The influence of thyroid surgery and radioiodine therapy on Graves' ophthalmopathy is controversial. Some contend that subtotal thyroidectomy exacerbates ophthalmopathy[1,2] and that ocular involvement could contraindicate surgery. Others have shown that neither treatment alters the course of Graves' ophthalmopathy[3–7].

Many studies have used inaccurate and subjective measures of little value[2,3,6], and disparate and short-term follow-up[7,8]. The present study used an objective measuring system to compare the effects of subtotal thyroidectomy and iodine-131 on Graves' ophthalmopathy by clinical and radiological evaluation of the orbit.

Patients and methods

Forty-five patients (90 orbits) with Graves' ophthalmopathy were studied. Twenty-one patients (42 orbits) were treated by subtotal thyroidectomy (group 1; six men and 15 women, mean age 32 (range 18–59) years) and 24 (48 orbits) with iodine-131 to a total dose of 5–20 mCi (group 2; eight men and 16 women, mean age 39 (range 22–65) years).

The choice of treatment was determined according to criteria published in the survey of medical strategies for the management of Graves' disease in Europe[9].

All patients underwent morphological and thyroid function tests, verification of smoking history, ophthalmological examination, ocular status categorization according to the American Thyroid Association classification[10] and were scored using the Feldon scale (evaluation of seven clinical signs: proptosis, lid retraction, lagophthalmos, vertical and horizontal oculomotor dysfunction, optic nerve involvement and periorbital oedema)[11,12]. They also underwent axial and coronal computed tomography (CT) before surgery or iodine-131 therapy, and 12 months after treatment.

Each patient received antithyroid drugs and β-blockers over a 1–3-year period from the onset of hyperthyroidism to the initiation of the prescribed treatment.

Paired and unpaired t tests were used, where appropriate, to compare the differences between various groups. $P < 0\cdot05$ was considered significant.

Radiology

A Somatom DR2-Siemens high-resolution scanner (Siemens, Munich, Germany) was used to perform the orbital scans.

CT was carried out with use of a 25-cm field of view, a 256-image matrix, a window width and level setting of 350 and 70 units respectively, and a magnification factor of 2·0. Measurements obtained directly from CT images were converted to true size using a scalimeter. Axial views were obtained parallel to the orbitomeatal line. Supine direct coronal images were obtained with variable angles to avoid dental amalgam or because of limitation in neck mobility. Ninety orbits were scanned with contiguous 2-mm thick sections.

Maximum horizontal diameters of the bellies of the medial and lateral rectus muscles were measured from axial scans. Maximum vertical diameters of the inferior rectus and superior muscle group (superior rectus and levator palpebrae superioris) were measured from direct coronal images.

The degree of proptosis was calculated by measuring the perpendicular distance from the anterior globe margin to the interzygomatic line on axial scans at the midglobe level.

Results

Clinical findings at 12 months based on the American Thyroid Association classification showed improvement in 34 orbits in group 1. Eight orbits remained unchanged and there was no instance of deterioration. In group 2 improvement was seen in eight orbits, no change in 28 and deterioration in 12 (*Figure 1*). The degree of proptosis estimated by Hertel exophthalmometry showed significant improvement in group 1 12 months after treatment ($P < 0\cdot001$). This was not seen in patients in group 2 (*Figure 2*).

The Feldon score indicated significant amelioration in both groups (group 1, $P < 0\cdot001$; group 2, $P < 0\cdot05$).

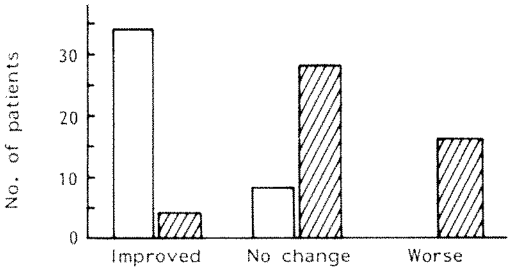

Figure 2 *Change in the degree of proptosis at 12 months after surgery (□) or radioiodine therapy (▨), assessed using Hertel exophthalmometry*

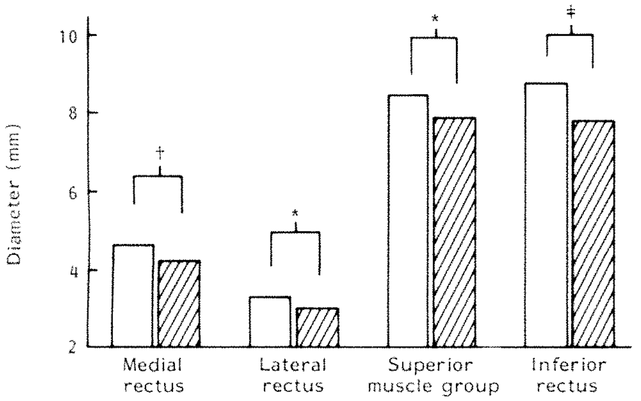

Figure 3 *Computed tomographic assessment of the mean maximum diameter of extraocular muscles in patients undergoing subtotal thyroidectomy, before (□) and 12 months after (▨) surgery.* *$P < 0{\cdot}05$; †$P < 0{\cdot}01$; ‡$P < 0{\cdot}001$ *(Student's paired* t *test)*

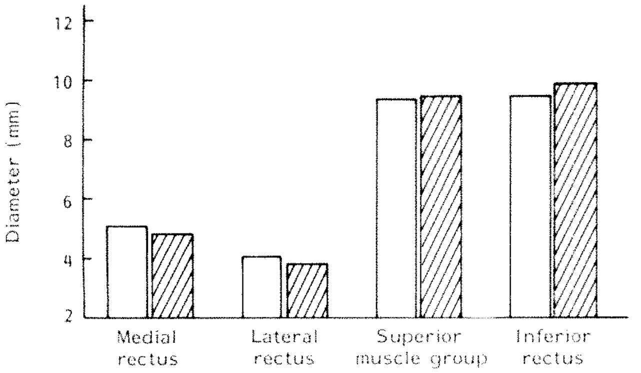

Figure 4 *Computed tomographic assessment of the mean maximum diameter of extraocular muscles in patients receiving radioiodine therapy, before (□) and 12 months after (▨) treatment. There were no statistically significant differences*

Results of the assessment of extraocular muscles and degree of proptosis by CT are shown in *Figures 3–5*. No significant improvement following treatment was seen in group 2 in the CT analysis.

Improvement in the degree of proptosis estimated by CT was significantly greater in group 1 than in group 2 12 months after treatment ($P < 0{\cdot}01$).

No correlation was found between change of ocular status and smoking history.

Thyroid status and replacement therapy at 12 months were as follows. In group 1, five patients became euthyroid without treatment and 16 euthyroid with L-thyroxine (three received 50 μg/day, ten 100 μg/day, three 150 μg/day). In group 2, four patients became euthyroid without treatment, one was hypothyroid with L-thyroxine (50 μg/day) and 19 remained hyperthyroid with thyroxine but became euthyroid with carbimazole or methimazole (three with low doses, 0–15 mg/day; 12 with medium doses, 16–30 mg/day; four with high doses, >30 mg/day).

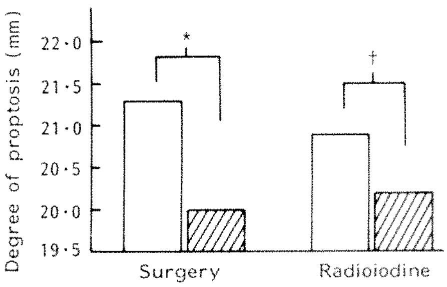

Figure 5 *Computed tomographic assessment of the mean degree of proptosis in the two groups of patients before (□) and 12 months after (▨) treatment.* *$P < 0{\cdot}001$; †P *not significant (Student's paired* t *test)*

Discussion

Since Naffziger[1] reported ocular exacerbation following thyroidectomy in one patient in 1931, others have described similar effects[2]. Evaluations have usually been based on the degree of proptosis estimated by Hertel exophthalmometry. Others have reported that thyroidectomy has no effect on the development of Graves' ophthalmopathy[3–7,13]. Similar controversy exists regarding the use of radioiodine therapy[5,6,13–16].

Various imaging techniques[7,11,12,17–19] allow objective evaluation of the course of Graves' ophthalmopathy. The latest CT scanners generate two-dimensional high-resolution images, making it possible to distinguish extraocular muscles, optic nerve, tear gland and bony orbit in axial and coronal sections.

The present study has shown a beneficial ocular response in patients undergoing surgery, with a decrease in the largest diameter of each of the extraocular muscles and in the degree of proptosis estimated by both CT and Hertel exophthalmometry.

Although patients receiving radioiodine therapy improved or remained unchanged, the amount of improvement was not significant, with the exception of the Feldon score. The dosage of radioiodine used to control hyperthyroidism has varied in the past few years, tending towards the use of ablative doses. However, as advised by Kendall-Taylor[13], repeated low doses are used by the present authors because hyperthyroidism should not be treated with an ablative dose of radioiodine if the patient has features of ophthalmopathy.

The present results indicate that neither therapy exacerbates ophthalmopathy and that subtotal thyroidectomy leads to significant improvement in the extraocular musculature. This is particularly so for both the medial and inferior rectus muscles, which are the two most affected in Graves' ophthalmopathy[17–19]. The Hertel exophthalmometer[7] is capable of producing results comparable to those estimated by CT in the evaluation of proptosis following treatment. Its advantages include easy use and minimal cost; its disadvantage is that it cannot be used to evaluate internal structures.

Surgical treatment produces improvement in Graves' ophthalmopathy. Longer term studies are required.

The detection of metastases in patients presenting with primary breast cancer alters prognosis and may significantly affect management. The extent of evaluation before treatment, however, in patients with apparently localized disease remains controversial. Although medical history, physical examination, chest radiography, full blood count and liver function tests are considered important[1], imaging techniques such as bone and liver scintigraphy have a low yield in asymptomatic patients[2,3]. The value of computed tomography (CT) has not been established. This study examined whether CT enabled cost-effective detection of metastases in the management of these patients.

Patients and methods

A retrospective review of the findings and outcome of 117 patients with apparently localized breast cancer presenting between August 1988 and October 1991 was carried out. CT of the head, chest, abdomen and pelvis was performed within 3 months of definitive breast surgery using a Siemens Somatom DRH scanner (Siemens, Erlangen, Germany). Continuous sections from brain to pubic symphysis with dynamic mode and intravenous contrast were used and assessed on bone, lung and soft tissue windows. Reporting was by one of five consultant radiologists as part of the routine workload. Other investigations are shown in *Figure 1*. Most patients had disease of early tumour stage (T_1, 38; T_2, 51; T_3, 16; T_4, 12), and nodal involvement rose proportionately with increasing T stage. Follow-up ranged from 6 to 42 (median 20) months.

Results

The yield of the different staging investigations and their relative cost are shown in *Figure 1*. CT detected metastases in only 4 per cent of patients overall (1 per cent–one of 89–for $T_{1/2}$ tumours). It detected only 50 per cent of proven metastases, had no higher yield than other investigations and did not positively affect management in these patients. There were 16 unrelated findings, mainly in the head and pelvis, where no metastases were found. These included two meningiomas (patients under observation) and four ovarian masses (three benign cysts at laparotomy and one presumed cyst, unchanged on follow-up CT).

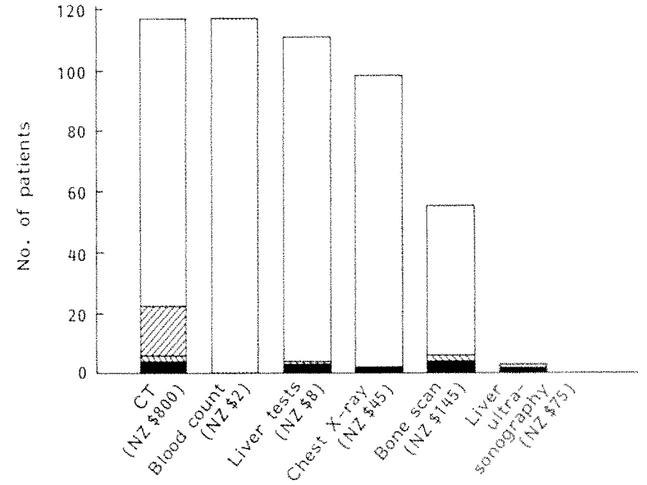

Figure 1 *Frequency of true metastases, false-positive and unrelated findings identified by the various investigations. The cost for each test is shown. CT, computed tomography.* ■, *Metastases correctly identified;* ▧, *false-positive scans;* ▨, *unrelated findings;* ⬚, *normal findings*

Two patients had false-positive scans, leading to unnecessary laparotomy in one and delay of definitive locoregional treatment in the other. CT failed to identify metastases detected by other investigations in four patients: three on bone scintigraphy (only one outside the CT field) and one with hepatic secondaries detected by abnormal biochemistry and positive liver ultrasonography.

Of those receiving definitive local treatment and with a normal scan there have been 18 relapses, eight within 1 year of CT. Early relapse was not related to T stage or nodal status.

Discussion

CT is much more expensive, but has no higher yield, than basic investigations in detecting metastases in asymptomatic patients with primary breast cancer. Unrelated findings may lead to considerable anxiety and to unnecessary operations. False-positive findings similarly complicate management, and a negative CT scan does not preclude early relapse.

Dr R. Prêtre

The medical records of 15 patients found to have pneumoretroperitoneum in a 10-year period were reviewed. The cause of retroperitoneal emphysema was infection in six patients, trauma in five and iatrogenic in four. Emphysema was confined to the retroperitoneum in 11 patients, and extended to the mediastinum in four and to the soft tissue of the neck in three. Failure to diagnose pneumoretroperitoneum resulted in delayed intervention in two patients. One patient with pneumoretroperitoneum and pneumoperitoneum secondary to a lung lesion underwent unnecessary laparotomy. Outcome was favourable in these three patients. The presence of air in the retroperitoneum is not dangerous but its early recognition and detection of the source are important as septic conditions may be involved.

The retroperitoneum communicates with the mediastinum and neck, and has extensions into the mesentery and abdominal wall (the preperitoneal space)[1]. Aberrant air in this space arises mainly from gastrointestinal or respiratory tract rupture and from gas-forming infections, and may diffuse to any one of these areas. Infiltration of air into the retroperitoneum has discrete diagnostic features. Its recognition is important since rupture of a segment of the gastrointestinal tract is frequently involved. Failure to identify this condition delays diagnosis and may result in significant sepsis. Awareness of the possible aetiology and anatomical routes in the retroperitoneum should help select appropriate diagnostic and surgical interventions.

Patients and methods

The medical records of 15 patients presenting with pneumoretroperitoneum between 1981 and 1990 were reviewed retrospectively. There were eight men and seven women of median age 64 (range 18–81) years. During the study period, 18 868 abdominal operations (14 766 elective, 4102 emergency) were performed in the same department. One of 3746 inguinal hernia repairs was complicated by colonic perforation leading to pneumoretroperitoneum. Four of 565 patients with colonic diverticulitis developed extensive pneumoretroperitoneum following perforation. Of 20 659 gastroscopies and 9210 colonoscopies performed, there was one instance of pneumoretroperitoneum after gastroscopy without biopsy and two after colonoscopy with biopsy. During the last 3 years of the study period additional procedures such as biopsy or polypectomy were performed in 55 per cent of all colonoscopies (1592 of 2905 procedures). No case of pneumoretroperitoneum was noted after approximately 250 endoscopic sphincterotomies, 162 of which were performed during the last 3 years of the study.

Results

Presentation

The causes of pneumoretroperitoneum are summarized in *Table 1*. Emphysema was confined to the retroperitoneum in 11 patients, and extended to the mediastinum in four and to the soft tissue of the neck in three. In one patient with a diverticular perforation at the rectosigmoid junction, air was not seen on plain abdominal radiography but was detected in the mediastinum and neck on chest radiography. The abnormal infiltration of air was detected without delay in 12 patients and its recognition prompted further radiological studies to identify the underlying disease and/or immediate surgical intervention. In three patients radiographic features were missed or falsely interpreted, resulting in delayed or inappropriate management.

Treatment

Pneumoretroperitoneum was managed medically by fasting, hydration and intravenous antibiotics in four patients: three had a gastrointestinal perforation following endoscopy (one duodenal, two rectal) and one had a duodenal stump leak. Conservative treatment seemed appropriate in patients with endoscopic perforation of the colorectum provided there were no signs of active infection since the bowel had been prepared and had no underlying stenotic lesion (*Figure 1*). Fatal sepsis developed in two patients who were denied surgical intervention because of their poor state of health and grave prognosis: one patient with a rectal perforation following biopsy had Child's grade C alcoholic cirrhosis and the other had undergone a palliative Billroth II gastrectomy 10 weeks previously for antral adenocarcinoma (T_4N_3).

Surgical management included procedures to treat the cause of the pneumoretroperitoneum and to drain a focus of infection when present. Hartmann's procedure was performed in four patients with perforated diverticulitis and in one with an iatrogenic lesion of the sigmoid colon following inguinal hernia repair. Colostomy, rectal wash-out, debridement and perirectal drainage were performed in three patients with an extensive perineal wound. Laparotomy ruled out associated abdominal lesions and confirmed the pneumoretroperitoneum. Removal of the prosthesis, local drainage and systemic antibiotic therapy were successful in a patient with an infected hip prosthesis that had produced sufficient gas to extend along the psoas muscle (*Figure 2*).

Delayed or erroneous diagnosis

Three patients had a delayed or false diagnosis.

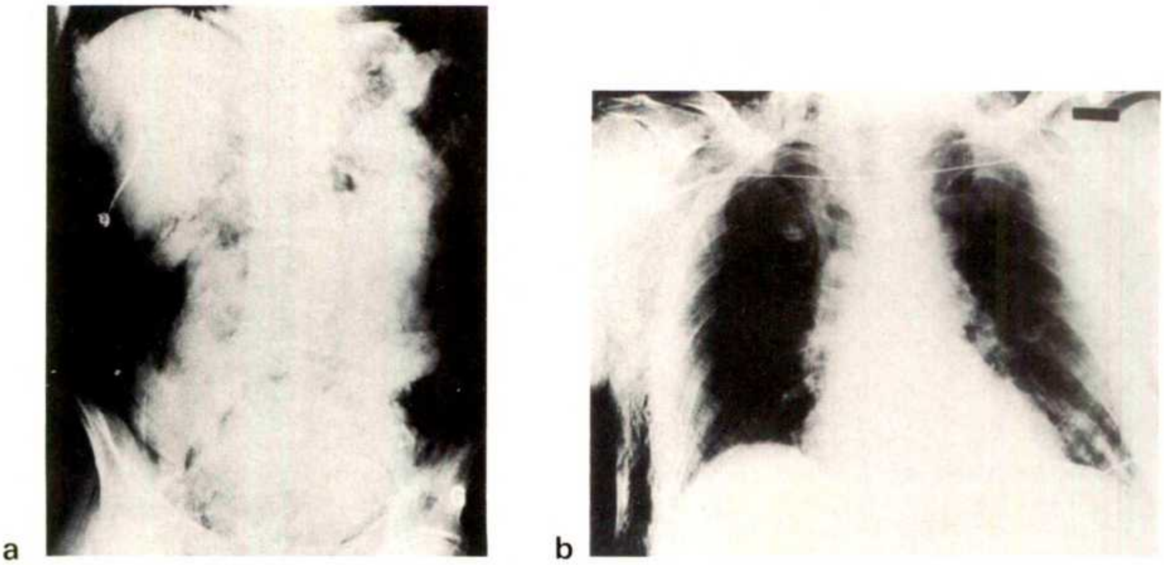

Figure 1 *Extensive emphysema following colonoscopy with biopsy of the rectosigmoid junction in a 75-year-old man.* **a** *Abdominal radiography shows pneumoretroperitoneum with some of the pelvic structures and the psoas muscle 'dissected' by air infiltration.* **b** *Pneumomediastinum and emphysema in the neck and the thoracic wall are visible on the chest radiograph*

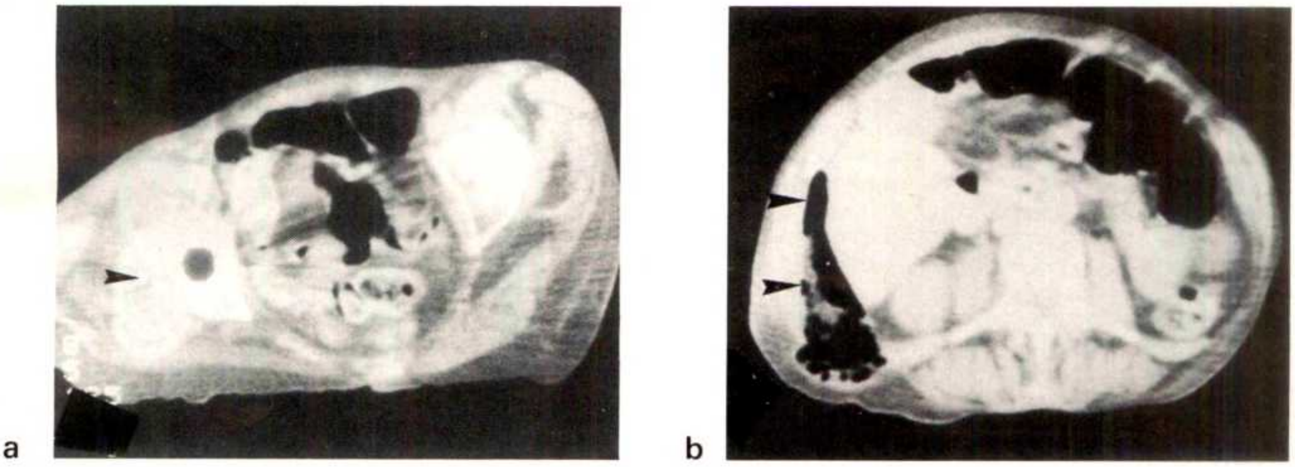

Figure 2 *Computed tomograms of the* **a** *pelvis and* **b** *abdomen of a 67-year-old woman with a prosthetic hip infection. In the pelvic image an abscess (arrow) surrounds the prosthesis. The abdominal image shows air infiltration in the retroperitoneum and in the preperitoneal space (arrows) of the abdominal wall between the transversalis fascia and the parietal peritoneum*

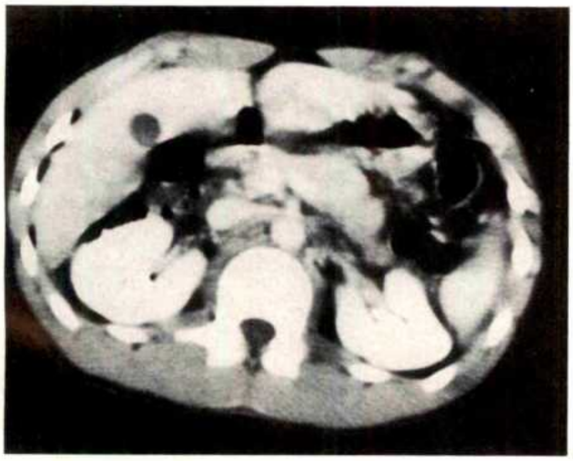

Figure 3 *Computed tomogram of a 19-year-old man (patient 1) with blunt abdominal trauma and perforation of the second part of the duodenum. Air infiltrated the retroperitoneum, as can be seen around the kidneys. This was missed initially and resulted in delayed treatment of the duodenal tear*

Patient 1. A 19-year-old man was involved in a motorcycle accident. Pneumoretroperitoneum adjacent to the duodenum, although visible on computed tomography, was missed initially (*Figure 3*). Some 2 days later the patient became feverish with signs of ileus and a repeat scan showed a retroperitoneal collection close to a duodenal perforation. At operation, a tear in the second part of the duodenum was confirmed. Despite surrounding retroperitonitis the duodenal perforation was closed primarily and the area widely drained. A fistula through the drain track resolved spontaneously in 3 weeks.

Patient 2. An 81-year-old woman was transferred with sequential organ failure. Abdominal palpation, and rectal and pelvic examination revealed a tender mass in the left lower quadrant. Chest radiography showed pneumomediastinum and emphysema of the neck. The latter had been noticed 2 days earlier and attributed to the placement of a central line. Air in the retroperitoneum was not apparent on abdominal radiography. Laparotomy showed perforated sigmoid diverticulitis in the retroperitoneum and extensive pneumoretroperitoneum. Hartmann's procedure was performed and the retroperitoneum drained. The patient recovered rapidly; renal and respiratory function returned to normal.

Patient 3. A 31-year-old man was intubated at the scene of a car accident because of coma. The patient was ventilated manually during transportation. Chest radiography revealed pneumomediastinum and emphysema of the soft tissue of the neck. Computed tomography showed pneumoretroperitoneum and pneumoperitoneum. No lesions were seen in the chest or abdomen. Laryngoscopy, bronchoscopy and contrast studies excluded a tracheobronchial or oesophageal lesion. Exploratory laparotomy was undertaken but proved normal. The patient recovered uneventfully.

Discussion

The retroperitoneum is divided by fasciae that provide preferential ways through which gas or fluid may spread. The retroperitoneum communicates with the mediastinum (through the diaphragmatic hiatus) and with the femoral vessels and spermatic cord inferiorly, and is continuous with the mesenteric and preperitoneal interstitium. The mediastinum communicates with the bronchovascular interstitium (via the pulmonary hilar structures) and with the visceral space of the neck[1]. A continuum therefore exists connecting the visceral space of the neck, the mediastinum, the retroperitoneum, the mesenteric and testicular interstitia and the root of the lower extremities.

Emphysema of the retroperitoneum, mediastinum and visceral space of the neck may arise from three pathological situations: disruption of cutaneous or gastrointestinal mucosal barriers, infection with gas-forming organisms, and rupture of the respiratory tract or alveoli. The progression of gas in tissues is determined mainly by pressure gradients, tissue resistance and quantity of gas. The retroperitoneum and mediastinum are for the most part covered by an air-tight layer of mesothelial tissue. This layer may break under excessive pressure and result in pneumothorax and/or pneumoperitoneum. When the air leak is distant from the retroperitoneum, large quantities of air and a high pressure gradient are necessary for the emphysema to reach the retroperitoneum. Examples include blunt chest trauma with rupture of a major airway[2], mechanical ventilation and Boerhaave's syndrome[3].

Rupture of a retroperitoneal structure may occur spontaneously, as in perforated duodenal ulcer, ulcerative colitis[4] or colonic diverticulitis, and is usually confined to the abdomen because of a low pressure gradient. Pneumoretroperitoneum following endoscopic procedures is extensive, however, because of the high pressure gradient generated and the large volume of air insufflated; it is thus sometimes associated with pneumoperitoneum and pneumothorax[5].

The four largest emphysemas in the present series occurred after colonoscopy with biopsy (*Figure 1*), following vigorous manual ventilation, after a sigmoid perforation was left untreated for 10 days, and after a hip infection (*Figure 2*). In the last case the extent of dissection probably resulted from gas pressure within the abscess and the lytic action of bacterial enzymes. Pneumoretroperitoneum complicated gastroscopy in two reported cases[6,7] and in one patient in the present series. All three patients had undergone partial gastrectomy a few weeks previously and air probably travelled through adhesions at the anastomotic site into the retroperitoneum. Of note in the present series is the absence of pneumoretroperitoneum after endoscopic sphincterotomy. Small amounts of air may have infiltrated the retroperitoneum in some patients, remaining clinically quiescent and escaping detection by cholangiography.

Pneumoperitoneum may occasionally have a pulmonary origin when a major air leak and high pressure gradient have been produced. A peritoneal tap for pressure release is sometimes required in newborn babies with membrane hyaline disease who are ventilated with high pressures because of stiff premature lungs[8,9]. One of the present patients with blunt chest trauma developed extensive emphysema with pneumoperitoneum after vigorous mechanical ventilation. Evron *et al.*[2] reported a similar patient with pneumoperitoneum following a tension pneumothorax. Observation was carried out and saved the patient an unnecessary exploration.

Interstitia of the retroperitoneum, mediastinum and visceral space of the neck are 'crossroads' where gas and fluid of different origins may accumulate. Continuous fascial planes connect these areas, permitting aberrant air arising in any one of them to spread elsewhere. While such air is not in itself dangerous, prompt recognition of its origin is essential since serious septic conditions may be involved.

Anterior *versus* posterior reconstruction after transhiatal oesophagectomy: a randomized controlled trial

H. Bartels, S. Thorban and J. R. Siewert

Department of Surgery, Klinikum rechts der Isar, Technischen Universität München, Munich, Germany

Correspondence to:
Professor H. Bartels, Chirurgische Klinik und Poliklinik, Klinikum rechts der Isar, Ismaninger Straße 22, D-8000 München 80, Germany

In a prospective randomized trial the clinical results after transhiatal oesophagectomy with reconstruction in the anterior mediastinum (51 patients) or posterior mediastinum (45 patients) were compared. There were no differences in age, preoperative risk factors, tumour stage and local (surgical) complications between the two groups. However, reconstruction in the posterior mediastinum was associated with significantly fewer days spent in the intensive therapy unit (9 versus *14), fewer cardiopulmonary complications (13* versus *25 per cent) and lower mortality (30-day mortality rate 2* versus *6 per cent; hospital mortality rate 4* versus *10 per cent). These data show superiority of reconstruction in the posterior mediastinum after transhiatal oesophagectomy. This route is strongly recommended, particularly for patients with cardiopulmonary risk factors.*

Transhiatal oesophagectomy has become a valid alternative to the transthoracic approach for oesophageal resection[1–5]. Most authors agree that the indications for transhiatal oesophagectomy are adenocarcinoma of the distal oesophagus, early squamous cell carcinoma of the distal oesophagus ($T_{1/2}$ tumours) and benign conditions of the oesophagus that require resection such as caustic injuries[6–9].

After transhiatal resection the surgeon has the choice between reconstruction in the anterior or posterior mediastinum, provided complete macroscopic and microscopic tumour excision (R_0 resection) has been achieved. Reconstruction in the anterior mediastinum may be considered superior because it allows postoperative irradiation of the oesophageal bed. Recently, however, improvements in patient selection and resection techniques have decreased the rate of local tumour recurrence to below 10 per cent[10]. Furthermore, tumour recurrence was rarely found to cause obstruction of the interposed organ.

To investigate whether reconstruction in the anterior mediastinum offers any advantages over that in the posterior mediastinum, a randomized controlled trial was performed.

Patients and methods

This study was performed between 1 October 1986 and 31 December 1988. All patients with oesophageal carcinoma who underwent transhiatal oesophagectomy and reconstruction by gastric interposition were included (*Table 1*). Patients who received preoperative radiotherapy or chemotherapy and those with previous gastric resection who required colonic interposition were excluded.

A total of 96 patients met the inclusion criteria. In 79 transhiatal oesophagectomy was performed for adenocarcinoma of the distal oesophagus; 17 had early squamous cell carcinoma ($T_{1/2}$) of the distal oesophagus. Cervical oesophagogastrostomy was performed in all cases; this allowed the choice between reconstruction in the anterior or posterior mediastinum. After obtaining informed consent the route of reconstruction (anterior or posterior mediastinum) was chosen in a random fashion before operation.

Age, tumour type and stage, and preoperative risk factors are shown in *Tables 2* and *3*. There were no significant differences between patients who had anterior or posterior reconstruction. All patients underwent R_0 resection, i.e. complete macroscopic and microscopic tumour removal.

Transhiatal oesophagectomy was performed in a standardized fashion as described previously[5,9,11]. After blunt dissection the gastric tube created parallel to the major curvature was interposed either

retrosternally (anterior mediastinum) or in the oesophageal bed (posterior mediastinum). Postoperative management was similar for both groups and included positive-pressure ventilation for 48 h after the procedure[12].

All intraoperative and postoperative data (duration of anaesthesia, blood loss, cardiopulmonary function, days in the intensive therapy unit, etc.), postoperative complications (surgical and other) and mortality were documented prospectively and evaluated at the end of the study. Details of the assessment of cardiopulmonary function are described elsewhere[13]. Student's t test, the Wilcoxon signed rank test and χ^2 analysis were used for statistical evaluation. $P < 0.05$ was considered significant.

Results

According to the preoperative randomization, 51 patients underwent reconstruction in the posterior and 45 reconstruction in the anterior mediastinum. The duration of anaesthesia and volume of intraoperative blood loss were similar in the two groups (*Table 4*).

In both groups the intrapulmonary right–left shunt (Q_S:Q_T) was markedly increased during the immediate postoperative period compared with preoperative values (*Figure 1*). The peak in shunt volume was seen 12 h after the procedure. Compared with that after reconstruction in the anterior mediastinum, respiratory function was less compromised in patients who underwent posterior reconstruction. This difference was significant 24 h after operation.

In addition, the cardiac index was significantly decreased throughout the first 36 h after operation in patients with reconstruction in the anterior mediastinum (*Figure 2*). This decrease in cardiac index was due primarily to a reduction in stroke volume index, which was compromised throughout the postoperative monitoring period in these patients (*Figure 3*).

Values in parentheses are percentages

The clinical data are shown in *Tables 4* and 5. Compared with anterior reconstruction, the posterior mediastinum procedure was associated with fewer days in the intensive therapy unit (9 *versus* 14), decreased frequency of general complications (13 *versus* 25 per cent) and lower mortality

(30-day mortality rate 2 *versus* 6 per cent; hospital mortality rate 4 *versus* 10 per cent).

Discussion

A lower complication rate has been claimed repeatedly for transhiatal oesophagectomy compared with the transthoracic approach[2-4]. To date, however, a decreased risk for transhiatal oesophagectomy could not be confirmed in clinical trials[14-16]. Rather, the decrease in postoperative mortality rate following oesophageal resection in recent years appears to be due to improved patient selection, standardization of resection technique and advances in perioperative and postoperative care[17,18]. These factors have a similar influence on transthoracic and transhiatal procedures[19].

According to the principles of oncological surgery, reconstruction in the oesophageal bed, i.e. the posterior mediastinum, should be attempted only after R_0 resection. In patients with advanced disease or when complete tumour resection is questionable, reconstruction should be performed in the anterior mediastinum to avoid obstruction of the interposed organ by local tumour recurrence and to allow postoperative irradiation of the oesophageal bed[9,18]. Because of patient selection and the high rate of R_0 resection, local tumour recurrence was not likely in the present population[10]. A random preoperative allocation of the route of reconstruction could therefore be justified for the present study.

Re-establishment of gastrointestinal continuity by a gastric tube in the mediastinum results in mechanical compression of the adjacent lung[20,21]. In the present study this was reflected by an increase in the intrapulmonary right–left shunt (Q_S:Q_T) during the early postoperative period. In an experimental study Niederle *et al.*[6] have shown a significant increase in intrapulmonary shunting in animals who underwent reconstruction in the posterior mediastinum compared with those undergoing anterior reconstruction. There were no significant differences in respiratory function between the two routes of reconstruction in the present study (*Figure 1*). The prophylactic 48-h postoperative positive-pressure ventilation that was performed in all the present patients to reduce compression atelectasis may explain this observation[12,13,21].

In contrast to the lack of difference in respiratory function between the two routes of reconstruction, the present study showed differences in haemodynamic function. The cardiac index, the most important cardiac parameter, dropped markedly immediately after the surgical procedure. This drop was similar in both groups of patients and was probably secondary to hypoxia and the negative inotropic effect of anaesthesia[20,21]. There was, however, a marked delay in normalization of the cardiac index during the first days after anterior reconstruction (*Figure 2*). Obstruction of the right ventricle by the interposed gastric tube or paradoxical movements of the septum and the resulting compromise in stroke volume index may explain this observation[6].

The compromised cardiac and respiratory function during the postoperative period is reflected in the clinical results. Cardiorespiratory complications, intensive therapy unit stay and mortality rate were greater after reconstruction in the anterior mediastinum. Similar results have been reported by Nishi *et al.*[22] in a retrospective analysis. In that study reconstruction in the posterior mediastinum following transthoracic oesophagectomy resulted in a 50 per cent decrease of respiratory complications compared with anterior reconstruction.

In the present study the route of reconstruction did not influence the rate of surgical complications. The frequency of cervical anastomotic leaks was similar in both patient groups (*Table 5*). In most patients the leak closed spontaneously after drainage.

The present study shows no differences in levels of blood loss, duration of postoperative ventilation, and surgical complications between the two methods of reconstruction (*Tables 4* and *5*). Reconstruction in the posterior mediastinum, however, had some major advantages, including a lower rate of cardiorespiratory complications, a shorter stay in the intensive therapy unit and decreased hospital mortality rate. In addition, posterior reconstruction offers several other advantages. The procedure is easier and can be performed more quickly because the diameter of the thoracic inlet is wider posteriorly than anteriorly and the surgeon does not have to create a second tunnel. Also, the interposed organ protects the tracheobronchial tree by tamponading the posterior mediastinum. This may become important if the tracheobronchial system is injured during the procedure. Finally, in the authors' experience postoperative swallowing is better after posterior reconstruction and dilatation easier to perform. An exact analysis of these factors, however, requires further study.

In summary, the present study documents the superiority of reconstruction in the posterior mediastinum following transhiatal oesophagectomy compared with reconstruction in the anterior mediastinum. Provided R_0 resection has been performed, posterior reconstruction should be the procedure of choice, particularly in patients at increased cardiorespiratory risk.

Announcement

Surgery of the Liver, Biliary System and Pancreas

The British Council are holding a course devoted to Surgery of the Liver, Biliary System and Pancreas in The Royal College of Surgeons of Edinburgh from 17 to 23 October 1993. The course is intended for discussion of complex issues with an audience composed of relatively senior specialist surgeons. Topics to be covered will include: cholelithiasis and choledocholithiasis; minimally invasive hepatobiliary surgery; transplantation of liver and pancreas; acute and chronic pancreatitis; pancreatic and periampullary cancer; hepatobiliary trauma; portal hypertension; and hepatic and biliary malignancy. The course will be directed by Professor D. C. Carter, University Department of Surgery, The Royal Infirmary, Edinburgh.

Further information can be obtained from: Courses Department, The British Council, 10 Spring Gardens, London SW1A 2BN, UK.

Venous thromboprophylaxis in oesophageal cancer surgery

In a retrospective study of 127 patients who underwent resection for oesophageal cancer without anticoagulant thromboprophylaxis, the incidence of clinically established postoperative deep vein thrombosis (DVT) was 1·6 per cent. In a prospective study the Sue-Ling DVT risk factor index was calculated for 53 consecutive patients with oesophageal cancer; the mean(s.d.) value was $-4\cdot4(3\cdot5)$. For 29 patients who underwent resection the following policy of thromboprophylaxis was applied. Patients undergoing transthoracic oesophagectomy with risk score > -4 (four patients) and those undergoing transhiatal resection with risk score > -1 (four) received both anticoagulant and mechanical thromboprophylaxis; the remaining 21 patients received only mechanical thromboprophylaxis. No patient developed DVT after operation. There were no haemorrhagic complications in the group undergoing anticoagulant thromboprophylaxis. The selective approach, based on the Sue-Ling risk factor index and type of operation, spared 72 per cent of the patients operated on from undergoing anticoagulant thromboprophylaxis and produced favourable results in this small series.

Oesophagectomy with reconstruction is a long and extensive procedure that is followed by a relatively lengthy period of bed-rest. The majority of patients are smokers and over 50 years old. All these factors increase the incidence of deep vein thrombosis (DVT)[1–4], and patients undergoing surgery for oesophageal cancer require thromboprophylaxis. Despite this, we believe that venous thromboembolic disease is not a common complication of oesophageal cancer surgery and that general anticoagulant thromboprophylaxis may not be required. The aims of this study were to estimate the risk of DVT in patients with oesophageal carcinoma and to evaluate the incidence of DVT and pulmonary embolism after oesophageal cancer surgery using a selective anticoagulant thromboprophylaxis regimen.

Patients and methods

The first part of the study was retrospective and based on 127 patients with oesophageal cancer (91 men, 36 women; mean(s.d.) age 58·7(7·9) years) who underwent oesophagectomy with cervical oesophagogastrostomy without anticoagulant thromboprophylaxis between 1979 and 1991. Clinical records and pathology reports were reviewed in detail and data regarding postoperative DVT and embolism recorded. Five patients received mechanical thromboprophylaxis with graduated compression stockings and all patients underwent early exercise and ambulation. The diagnosis of DVT and embolism was based on clinical grounds and/or findings at autopsy.

The second part of the study was prospective and based on 53 consecutive patients with oesophageal cancer (36 men, 17 women; mean(s.d.) age 60·9(8·2) years) treated during 1991. A DVT risk factor index (I) was calculated using the formula of Sue-Ling *et al.*[5]:

$$I = -8\cdot08 + 0\cdot185a + 0\cdot008b - 2\cdot24c + 2\cdot02d - 0\cdot054e - 0\cdot118f - 0\cdot006g$$

where a is age in years, b is euglobulin lysis time in minutes, c is previous abdominal surgery (yes, 1; no, 0), d is presence of varicose veins (present, 1; absent, 0), e is amount of antithrombin III as a percentage, f is number of cigarettes smoked per day, and g is platelet count ($\times 10^6$ per millilitre). A shortened predictive index was calculated as follows:

$$I_S = -11\cdot5 + 0\cdot133a + 0\cdot006b$$

Laboratory methods were the same as those used by Sue-Ling *et al.*[5] and Blix[6] except for the concentration of antithrombin III, which was measured using an enzyme-linked immunosorbent assay photometer (Behring, Frankfurt, Germany).

Of the 53 patients, 29 underwent potentially curative resection. Ten who had tumours of the middle third of the oesophagus and were in good general condition underwent oesophagectomy through a right thoracotomy. The remaining 19 underwent oesophagectomy by blunt dissection. All 29 patients underwent reconstruction with the stomach anastomosed to the cervical oesophagus, and all received mechanical thromboprophylaxis.

Sue-Ling *et al.*[5] reported that patients with large positive scores are most likely to have postoperative DVT, that 91 per cent of patients with DVT are correctly identified if a cut-off value of -1 is used, and that no DVT occurs among those with risk score < -4. The policy in the present study of selective anticoagulant thromboprophylaxis was based on these observations and the perceived risk of haemorrhagic complications. The thoracic approach provides good control of haemostasis, and for patients undergoing transthoracic oesophagectomy a cut-off value of -4 was used; four of the ten patients had a risk score > -4 and received anticoagulant thromboprophylaxis. Control of haemostasis can be problematic in blunt oesophageal resection and it was felt that anticoagulant thromboprophylaxis might increase the frequency of haemorrhagic complications; for the 19 patients undergoing blunt oesophagectomy a cut-off value of -1 was used. Four of these patients had a risk score > -1 and received anticoagulant thromboprophylaxis; the remaining 15 did not.

Anticoagulant thromboprophylaxis consisted of low-dose heparin (5000 units) given subcutaneously 2 h before surgery and then at intervals of 12 h. Mechanical thromboprophylaxis included graduated compression stockings, and early exercise and ambulation.

All patients underwent clinical surveillance and real-time duplex B-mode ultrasonography (Toshiba SSA-100A; Toshiba, Tokyo, Japan) using a 3·5-MHz and 7-MHz probe for DVT, both before and after operation. Ultrasonography was performed in 11 patients twice after operation: the first time on days 4–5 after surgery and the second time on days 9–12. In the remaining 18 patients ultrasonography was performed only once, 8–12 days after operation. All duplex scans were performed by the same experienced operator (Z. M.).

Results

Among the patients analysed retrospectively who were operated on without anticoagulant thromboprophylaxis, the incidence of clinically manifested DVT and/or embolism was two of 127 (1·6 per cent). One patient died from pulmonary thromboembolism; diagnosis was based on clinical symptoms and confirmed by autopsy, which identified a clinically silent DVT of the leg as the source of emboli. Clinically symptomatic DVT

Presented at Eurosurgery '92 in Brussels, Belgium, and published in abstract form as Br J Surg *1992;* **79**: *S104*

0007-1323/93/091145-02 © 1993 Butterworth-Heinemann Ltd

of the calf occurred in a further patient who was successfully treated conservatively.

The mean(s.d.) euglobin lysis time for the 53 patients with oesophageal cancer was 198(73) min, and the mean(s.d.) DVT risk factor index was $-4{\cdot}4(3{\cdot}5)$. Four patients (8 per cent) had a positive index, 45 (85 per cent) had an index < -1, and 30 (57 per cent) had an index < -4; the 95 per cent confidence interval for the DVT risk factor index values obtained was $-10{\cdot}20$ to $1{\cdot}05$. The mean(s.d.) value of the shortened predictive index was also low, $-2{\cdot}7(1{\cdot}0)$. It has been shown[5] that at a cut-off value of $-1{\cdot}5$ this index has a sensitivity of 93 per cent and a specificity of 83 per cent. Of the 53 patients, only two had a shortened predictive index $> -1{\cdot}5$. All patients who underwent resection had a shortened index $< -1{\cdot}5$.

None of the 29 patients undergoing resection developed clinically or ultrasonographically detectable DVT after operation. There were no haemorrhagic complications in the group receiving anticoagulant thromboprophylaxis.

Discussion

It has been suggested that routine anticoagulant thromboprophylaxis in major general abdominal surgery minimizes the incidence of thromboembolic complications and is cost-effective, whereas selective treatment is unsatisfactory and expensive[7,8]. However, anticoagulant thromboprophylaxis may also increase the frequency of haemorrhagic complications[9,10]. Although there are no published data on this issue, it might be anticipated that routine anticoagulant thromboprophylaxis may even be dangerous for patients who undergo blunt oesophageal resection. Control of haemostasis is generally delicate in these patients and the average intraoperative blood loss[11], even without thromboprophylaxis, is about 1000 ml.

Larger series describing results of oesophageal cancer resection have shown that the incidence of postoperative thromboembolic complications rarely exceeds 1 per cent[11,12]. A similar incidence was recorded in the present patients studied retrospectively, who received no anticoagulant thromboprophylaxis. Although it should be emphasized that the real incidence of DVT is much higher than can be appreciated from a retrospective study, the vast majority of the present patients with oesophageal cancer were found to have a low DVT risk factor index and shortened predictive index. It seems unlikely that patients with oesophageal cancer are at particularly high risk for postoperative DVT.

Mechanical thromboprophylaxis has recently been shown in general surgical patients to be as effective as anticoagulant therapy[13]. Hence, weighing the risk of developing thrombosis against the benefits, cost and potential complications of general anticoagulant thromboprophylaxis, a selective approach to anticoagulation in oesophageal cancer surgery seems justified if it proves possible to identify correctly the small subset of patients who are likely to develop DVT. A similar effect would be achieved by identification of those who are unlikely to develop DVT; they could safely be spared anticoagulant thromboprophylaxis.

In the present series, the mean(s.d.) age, euglobin lysis time, DVT risk factor index and shortened predictive index were similar to the values obtained by Sue-Ling *et al.*[5], which suggests that the results should be comparable. Hence, the selective approach based on the Sue-Ling risk factor index and type of operation seemed safe and reasonable. Such a regimen spared 21 of the 29 patients undergoing operation from anticoagulant thromboprophylaxis and produced favourable results in this small series. However, duplex scanning may have missed some small distal thrombi. Although the total incidence of DVT in the present series may have been underestimated, such thrombi are probably not of great clinical significance.

The present preliminary findings suggest that there is a potential case for selective anticoagulant thromboprophylaxis in patients undergoing surgery for oesophageal cancer. The risk factor index can be calculated rapidly, which is especially useful to surgeons with a heavy clinical load. Larger controlled studies are necessary to define more accurately the best thromboprophylactic regimen for the patient with oesophageal cancer who undergoes surgery.

Dr C. Hatzitheofilou

Fifty-one instances of oesophageal perforation were discovered when the records of 18 588 patients with external penetrating injuries of the neck, chest and abdomen were reviewed. Of these, 33 resulted from stab wounds, 17 from bullets and one from hyperextension of the neck. There were 15 perforations of the pharynx and 36 of the oesophagus. Oesophagography in a lateral decubitus position demonstrated the perforation in all 16 patients in whom it was used. In 45 patients simple repair within 24 h of injury was performed (mortality rate 11 per cent). In six patients with a delay of more than 24 h in the repair of the thoracic oesophagus, special techniques were preferred. In two patients an oesophageal diversion–exclusion method was used; one such patient died. In four patients repair over a large-bore T tube was carried out with one death. The main cause of mortality was associated spinal injury (four deaths).

A large number of patients with penetrating injuries of the neck, chest and abdomen are treated at Baragwanath Hospital. The oesophagus is rarely injured because of its central and relatively protected position. Early investigation and repair of potential oesophageal injuries is of importance: several studies have shown substantially higher mortality rates following repair delayed more than 24 h from the time of injury[1,2].

Patients and methods

The records of all patients with trauma to the neck, chest or abdomen presenting between January 1988 and December 1991 were reviewed retrospectively for oesophageal injuries. All external injuries were examined but internal trauma such as iatrogenic perforation was excluded. The neck was surgically explored only when certain criteria were met[3]. The indications for thoracotomy in the case of chest or neck injury have been described elsewhere[4]. Oesophagography or oesophagoscopy was carried out if: (1) a penetrating injury of the neck or chest was anatomically directed towards the oesophagus; and (2) there were no indications for immediate surgical exploration. The need for oesophagography or oesophagoscopy was considered more compelling when clinical findings (surgical emphysema, dysphagia, haematemesis) or radiological results (surgical emphysema, haemopneumothorax, widening of the mediastinum, increased distance from trachea to vertebral column) were suspicious of, or compatible with, oesophageal perforation. Water-soluble contrast media were preferred since Gastrografin (Berlimed, Johannesburg, South Africa) can produce severe irritation in the airway and lungs.

Injuries of the abdominal oesophagus were discovered at laparotomy undertaken in patients with an acute abdomen.

A nasogastric tube was usually introduced and the neck explored through an incision along the anterior border of the sternomastoid. When less than 24 h had elapsed between injury and surgery, primary repair of the oesophagus was performed, usually with a single layer of interrupted non-absorbable sutures. After more than 24 h oesophageal diversion and exclusion as described by Johnson *et al.*[5] was added. Jejunostomy rather than gastrostomy was used. In one patient the proximal stump of the divided cervical oesophagus would not reach the skin and a tube oesophagostomy was constructed.

T tube splinting was recently introduced for late repair. A large 22–24-Fr tube was inserted via the perforation and the ends of its limbs cut to project 2·5 cm above and below the lesion[6]. The long limb was brought out through the chest wall. The perforation was closed above and below the tube with single all-layer interrupted sutures. This method has already been used in earlier years to treat 'spontaneous' rupture of the oesophagus[7].

Results

Review of the records of 440 patients with neck, 8688 with thoracic and 9460 with abdominal penetrating injuries produced 51 subjects with external oesophageal perforation. There were 49 male and two female patients of mean age 25·6 (range 11–56) years. This was less than the mean age of patients with iatrogenic internal perforation (59·5 years) seen over the same period[8].

The 51 injuries represented 33 stabbings, 17 bullet wounds and one hyperextension blunt injury (as already described[9]). The location and type of the injuries are presented in *Table 1*. *Table 2* shows the clinical findings and *Table 3* the radiological results.

Contrast oesophagography in a lateral decubitus position[10] was used in 16 patients and rigid oesophagoscopy in ten.

*Death from associated injuries

Oesophagography demonstrated the perforation in all patients but endoscopy was positive in only seven.

In 32 patients one or more of the general indications led to surgical exploration of a neck wound regardless of suspicion of oesophageal perforation (*Table 4*).

In perforation of the thoracic oesophagus the diagnosis was based on contrast oesophagography in five patients. Two patients with perforation of the abdominal oesophagus presented with an acute abdomen. Surgical emphysema was seen on radiography in seven patients with perforation of the pharynx, eight with perforation of the cervical oesophagus and two with perforation of the thoracic oesophagus.

At surgery in 18 patients the perforation was localized exactly by palpating a nasogastric tube through the gap of the perforated oesophageal wall. Use of methylene blue or following the track of the penetrating injury also facilitated its localization.

Table 5 shows mortality according to type and site of the perforation. In 45 patients with an interval from injury to operation less than 24 h, repair of the oesophagus was performed. In the majority, this was carried out with a single layer of interrupted non-absorbable sutures. Five of these patients died from associated injuries.

Six patients underwent repair after more than 24 h. One of two such patients treated by diversion–exclusion died. In four patients the oesophagus was repaired over a T tube; one of these patients died.

Of the 51 patients, 37 had 53 associated injuries of other organs, most of which had little bearing on mortality and morbidity. There were, however, five deaths resulting directly from associated trauma, four from injury to the spine and one from multiple intra-abdominal injuries. Sixteen complications occurred in 11 of the survivors: seven had oesophageal leakage, five pneumonia, two thrombophlebitis, one a neck haematoma and one a disorganized chest requiring lung decortication.

A large proportion of complications in patients who died were related to paraplegia: pneumonia (two), bed sores (two), aspiration (one), pulmonary embolism (one) and septic shock (one). Other complications unrelated to paraplegia were: pneumonia (one), leakage after T tube repair with fulminant mediastinitis (one), leakage after late repair (one), intra-abdominal sepsis (one), psychiatric problems with lack of motivation after a long convalescence (one) and malfunction of a jejunostomy (one).

Discussion

When neck exploration for penetrating trauma is planned because of positive general criteria, oesophagography is not necessary. Associated spinal injuries in the present series were the main cause of death. Those from delayed treatment were fewer. This might be attributed to the use of special surgical methods: repair with oesophageal diversion–exclusion and repair over a T tube. Repair with diversion–exclusion was associated with the problems already described.

In four patients where the delay from injury to repair had exceeded the 24-h limit by only a few hours T tube repair was used. Previous favourable reports of this method followed 'spontaneous' rupture of the Boerhaave type[7]. In the present series T tube repair was used for external penetrating injuries; the single death associated with this approach occurred in a patient treated after the development of fulminant mediastinitis[11]. This procedure should be assessed further as it has significant advantages: it is less time-consuming and does not require lengthy hospital stay with repeated surgical procedures. The method is clearly inappropriate where the tissues are extremely friable after a long delay.

There has been a trend away from non-operative conservative treatment for external penetrating injury of the oesophagus[12]. This is contrary to current practice for small iatrogenic perforation from flexible instruments. It is unclear whether simple surgical drainage of the injured area without repair of the oesophageal perforation is adequate[11].

Encasement of the bowel in a fibrous cocoon is a rare cause of intestinal obstruction[1,2] that can be part of a syndrome of generalized visceral fibrosis[2,3]. Two patients are reported, one a young man with associated liver cirrhosis, the other a woman with constrictive pericarditis and a history of taking propranolol.

Case reports

Patient 1

A 17-year-old man presented with acute intestinal obstruction. He had five previous hospital admissions for similar episodes that had settled with conservative treatment. Examination revealed a tender right paraumbilical mass. Abdominal radiography did not show obvious intestinal obstruction.

A provisional diagnosis of intermittent intussusception was made, and laparotomy was performed. The stomach and intestines were found to be encased in a thick fibrous cocoon, within which there were interloop adhesions of the intestines. Simple excision of the cocoon with lysis of the adhesions was performed.

The patient developed bleeding from oesophageal varices on the eighth day after operation; this responded to injection sclerotherapy. Liver biopsy revealed cirrhosis. The man was well on discharge.

Patient 2

A 43-year-old woman presented with abdominal pain associated with vomiting and constipation. She had had similar episodes over the previous 3 months that had resolved spontaneously. She also had orthopnoea and effort dyspnoea. The patient had been taking propranolol 40 mg twice daily for the previous 2 years for hypertension. Examination revealed raised jugular venous pressure and pulmonary oedema. There was an ill defined and tender lower abdominal mass. Radiography showed pericardial calcification and equivocal signs of intestinal obstruction.

At laparotomy the stomach, liver and intestines were found to be encased in a thick fibrous cocoon, about 0·5–2 mm thick, which was separate from the parietal peritoneum. There were soft fibrous adhesions between the encased bowel loops. The cocoon was easily peeled off, freeing the intestines. The patient made an uneventful recovery.

In both cases the excised cocoon was reported histopathologically to be a sheet of thick membranous hypocellular fibrous tissue with no evidence of inflammation or granuloma formation.

Discussion

The aetiology of abdominal cocoon remains obscure. The β-blockers have been implicated, in particular propranolol. This group of drugs lowers the adenosine 3′,5′-cyclic monophosphate: guanosine 3′,5′-cyclic monophosphate ratio which controls normal cellular proliferation; this may therefore initiate excessive proliferation[4]. Collagen production is suppressed *in vitro* by endogenous β-agonists. By interfering with this inhibition, β-blockers may lead to enhanced collagen production and subsequent fibrosis[5]. About 25 per cent of patients with sclerosing peritonitis induced by β-blockers have inflammatory involvement of another serous cavity such as the pleural space or pericardium[3], as in patient 2 with constrictive pericarditis.

The association of abdominal cocoon with liver cirrhosis has not been reported previously, and patient 1 is also unusual in being male[1].

Intestinal obstruction in these two patients was caused simply by kinking and compression of the intestines within the constricting cocoon and was completely relieved after cocoon excision. Bowel resection was unnecessary.

In a series of 128 patients operated on for gastric cancer, 27 satisfied microscopic criteria for radical resection. The median age of these patients was 72·3 (range 36–84) years at operation; the median hospital stay after surgery was 12·9 days. The median observation time was 3·8 years and the crude 5-year survival rate 48 per cent. Older patients did remarkably well. No significant difference was found in the number of survivors, survival–observation time or hospital stay in the age groups 55–64, 65–74 or 75–84 years. Thus, age alone should not be considered a barrier to curative surgical treatment. When the study was ended, 12 of the 27 patients who underwent microscopically confirmed radical resection were still alive; six had died from recurrent gastric cancer and nine from other causes. At 5 years after microscopically confirmed radical resection for gastric carcinoma, the gastric cancer-specific mortality rate was 23 per cent.

The age distribution of the population is changing in the West. In Denmark[1] the proportion of the population that is aged 65 years or more rose from 7 per cent of men and 8 per cent of women in 1940 to 13 and 17 per cent respectively in 1986. This has generated an interest in how well operations are tolerated by elderly patients.

Frederiksberg is an urban community of population approximately 86 000, with an over-representation of old people[2]: 18 per cent of men and 31 per cent of women are ≥65 years. Frederiksberg Hospital is the regional infirmary, to which all patients from the region are admitted.

In the West, adenocarcinoma of the stomach (excluding the oesophagogastric junction) affects mainly the elderly, and its incidence has declined over the past 40 years – in Denmark[3] from 1590 cases a year in 1943–1947 to 782 in 1978–1982. The prognosis is still poor, and considerations on this may postpone diagnosis and treatment, especially in elderly patients.

In this retrospective survey the toleration of older patients for surgery that met microscopic criteria for radical resection of gastric cancer was studied.

Patients and methods

A total of 129 patients underwent operation for primary adenocarcinoma of the stomach (other than the oesophagogastric region) during the period from January 1978 to December 1988. One patient was excluded because of concurrent cancer of the colon, leaving 128 patients with a median age at operation of 71·3 (range 36–91) years. There were 60 men (median age 68·5 (range 36–91) years) and 68 women (median age 74·5 (range 37–89) years), a male:female ratio of 0·88:1. The study was ended on 1 May 1991.

Routine practice was to perform the smallest resection consistent with a tumour-free margin of 5 cm; total gastrectomy was performed only if necessary to achieve this. All palpable lymph node metastases were excised, and when there were no palpable nodal metastases only the perigastric (group 1) lymph nodes were dissected (R_1 gastrectomy)[4].

All medical records were reviewed; most were complete and in the few cases where the histology report was missing the Institute of Pathology had a copy. At the end of the study 13 patients were still alive, with a median observation time of 2219 (range 992–3000) days, or approximately 6·1 years; 115 had died. None of the patients had emigrated, so that the time of all deaths could be confirmed from the Danish National Register, to which all Danish hospitals are connected. The cause of death was verified from the medical records in 103 patients, of whom 98 died at Frederiksberg Hospital and five at other Danish hospitals. In all those who died with proven recurrence, the cause of death was considered to have been gastric cancer, including ten patients who died at home with proven recurrence. Two patients died at home after 3·2 and 4·6 years respectively; one had not been to any hospital during this time, and the other had been hospitalized for a heart condition only. These two patients were considered to have died from other causes.

Analysis was performed with Medstat (Astra, Albertslund, Denmark), a personal computer database and a statistical package which include Kaplan–Meier life-table analysis for cumulated survival rates.

The age- and sex-matched expected survival rate based on national death statistics was estimated by the Danish Medical Research Council.

Results

A total of 68 resections were performed: five total gastrectomies and 63 other resections, of which 57 included approximately two-thirds and six only one-third of the stomach. In 60 patients the tumour was too widespread for resection; 17 underwent gastroenterostomy. Of the 68 resections, 20 were palliative, 48 macroscopically radical but only 27 radical on microscopic criteria ($N_0S_0P_0H_0$); none of the latter was a total gastrectomy. The distribution according to age and operability of the patients is shown in *Figure 1*.

The median age of the 27 patients who satisfied microscopic criteria for radical resection was 72·3 (range 36–84) years; there were 14 men and 13 women. Three patients had urgent surgery

*Values are median (range)

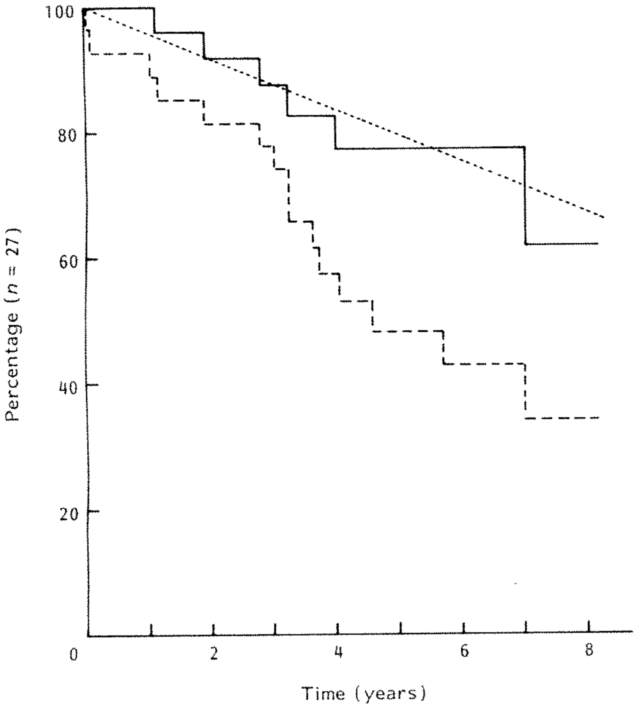

Figure 2 *Survival following microscopically confirmed radical resection in 27 patients operated on for gastric cancer, excluding that of the oesophagogastric junction.* ·····, *Age- and sex-matched expected survival rate based on the mortality rate of the Danish population;* – – –, *overall (crude) survival rate (Kaplan–Meier);* ——, *gastric cancer-specific mortality rate expressed as percentage not dead from recurrence (Kaplan–Meier; see text for details). After 5 years 11 patients were still at risk (Kaplan–Meier)*

for uncontrolled haemorrhage. Two patients died within the first 30 days after operation, resulting in a perioperative mortality rate of 7 per cent. There were no perioperative deaths among the 21 patients who had macroscopic clearance which was not confirmed microscopically.

The median observation–survival time for all patients undergoing microscopically confirmed radical resection was 1405 (range 5–3000) days, or approximately 3·8 years. Of the 27 patients, 12 are still alive with a median observation time of 2241 (range 1046–3000) days, or approximately 6·1 years, while 15 have died (including the perioperative deaths) after a median (range) survival time of 1185 (5–2564) days, or approximately 3·2 years, six from recurrence of gastric cancer (1102 (414–2564) days) and nine from other causes without known recurrence (1185 (5–2092) days). The crude survival rate was 82 per cent at 2 years, 48 per cent at 5 years and 34 per cent at 8 years (*Figure 2*).

The median length of stay in hospital after radical resection confirmed microscopically was 12·9 (range 5–34) days. *Table 1* shows the length of stay, the observation–survival time and cause of death in different age groups.

Discussion

The present survey has the disadvantage of all retrospective surveys: the results are poor from the standpoint of current technical abilities. All patients with gastric cancer are now evaluated using ultrasonography and/or computed tomography (CT) before elective operation, and examination of frozen sections of lymph nodes and resection margins is used to help determine the extent of resection. However, ultrasonography and CT were available in the department only during the last years of the study period, and frozen-section microscopy became routine only after that period. Given the small number of patients with gastric cancer operated on each year, it is too early to evaluate the results of these improvements. A reduction in the number of unnecessary laparotomies is to be expected, as well as an improvement in peroperative staging and thus in the outcome of operation for node-positive gastric cancer. However, routine practice is still to perform only R_1 gastrectomy in node-negative gastric cancer.

In the present series of 128 patients operated on for gastric cancer, 27 (21 per cent) underwent radical resection based on microscopic criteria. As in other Western series[5–12], at the time of diagnosis most of the tumours had spread beyond curative treatment. The perioperative mortality rate among all intended curative resections was 4 per cent (two of 48), which is similar to rates from other Western surveys[5–7,10,13–16]. Both of the perioperative deaths were in the first half of the period. The patients were aged 72 and 80 years; the latter was operated on urgently because of severe haemorrhage, and both had severe concurrent disease.

The toleration of elderly patients to operation is often evaluated by comparing the results in those above and below the age of 70 years[13,14,17]. However, this age limit seems arbitrary and, at least in the West, outdated. The older patients in this study did remarkably well. The numbers were small, but χ^2 analysis showed no significant difference in observation–survival time, hospital stay or number of survivors in the age groups 55–64, 65–74 and 75–84 years. Other Danish[18] and Swedish[19] surveys have also found that patients above 80 years tolerate operation well.

Different statistical methods have been used to evaluate the results after operation for gastric cancer. Most surveys give crude survival rates. The crude 5-year survival rate (Kaplan–Meier) after microscopically confirmed radical resection in the present study was 48 per cent, which is comparable to the rates of 24–45·5 per cent reported from other Western centres[5,6,9,10,14,16], including perioperative deaths.

The use of crude survival rates makes the prognosis seem even poorer, because many of the patients are old. Of the 27 patients with microscopically confirmed clearance in the present study, 15 died after a median survival time of 3·2 years. However, only six died from recurrent gastric cancer, while nine died from other causes. This problem may be solved by estimation of cancer-specific mortality by Kaplan–Meier life-table analysis, counting patients who died from causes other than recurrence as 'lost to follow up'. In the present survey, 5 years after the operation 77 per cent of patients with microscopically confirmed clearance had not died from recurrent gastric cancer, giving a cancer-specific 5-year mortality rate of 23 per cent.

In conclusion, 75–84-year-old patients did as well as those aged 65–74 or 55–64 years following microscopically complete R_1 resection for gastric cancer. When considering curative treatment, age alone should be no barrier to surgery. Instead of crude survival rates, it is suggested that cancer-specific mortality rates be used to determine the outcome of operation for gastric cancer.

Extensive *versus* limited lymph node dissection for gastric cancer: a comparative study of 320 patients

To compare extensive with limited lymph node dissection in the surgical treatment of gastric cancer, 320 patients undergoing gastric resection during 1981–1990 were divided into two groups. Although patients undergoing extended lymphadenectomy (n = *157*) *had a longer operating time* (P = *0·0001*) *and a greater intraoperative blood transfusion requirement* (P = *0·009*) *than those receiving limited dissection* (n = *163*), *the incidence of postoperative complications* (*22·3* versus *28·2 per cent,* P = *0·13*) *and the hospital mortality rate* (*3·8* versus *7·4 per cent,* P = *0·12*) *were similar in the two groups. The 5-year survival rate after curative resection* (*117 and 121 patients after extensive and limited lymph node dissection respectively*) *was 65·4* versus *50·1 per cent* (P = *0·01*)*: 85·9* versus *82·2 per cent for stage I disease* (P = *0·60*), *66·1* versus *57·8 per cent for stage II* (P = *0·82*) *and 48·7* versus *29·8 per cent for stage III* (P = *0·02*). *Multivariate analysis using the Cox model showed that the extent of lymphadenectomy was an independent prognostic factor for survival* (P = *0·01*). *The results support the value of extensive lymph node dissection in the surgical treatment of gastric carcinoma.*

Controversy still surrounds the value of extensive regional lymph node dissection in the curative treatment of gastric adenocarcinoma.

The R_2 and R_3 types of gastrectomy are routinely used in most operations for gastric cancer in Japan and, depending on the location of the primary tumour, these methods include removal of n2 and n3 as well as the perigastric (n1) lymph nodes[1–4]. This contrasts with surgical practice in the UK and USA where R_1 gastrectomy predominates and only the perigastric nodes are removed during gastric resection[5,6]. Resistance in the West to the use of more radical types of gastrectomy is based on uncertainty of the value of such procedures and on the unfavourable results of such operations in the USA 20 years ago[7].

The aim of the present study was to compare the results of extended lymphadenectomy with those of limited lymph node dissection in the surgical treatment of gastric carcinoma.

Patients and methods

A retrospective cohort study was carried out on 320 patients with histologically proven adenocarcinoma of the stomach who underwent resection during 1981–1990. Patients were admitted under the care of one of two surgical teams, depending on the availability of beds. The two teams adopted different policies: one routinely performed extended lymphadenectomy and the other limited lymph node dissection.

The group undergoing extensive dissection consisted of 157 patients operated on by one senior surgeon. Of these patients, 94 underwent total gastrectomy with R_3 lymphadenectomy as described by the Japanese Research Society for Gastric Cancer[8]. The entire greater omentum, superior leaf of the mesocolon, pancreatic capsule, lesser omentum, spleen and all perigastric nodes (nos 1–6 according to the Japanese classification) were removed *en bloc* with the stomach; lymphadenectomy was performed in the infraduodenal and supraduodenal areas, along the hepatic pedicle (node 12) and retropancreatic region (node 13), and along the common hepatic (node 8), coeliac (node 9), mesenteric (node 14) and splenic (node 11) arteries. The left gastric artery was ligated at its origin. The remaining 63 patients in this group underwent distal subtotal gastrectomy and R_2 lymphadenectomy extended to the hepatic pedicle and retropancreatic nodes.

The group undergoing limited lymph node dissection consisted of 163 patients who underwent R_1 gastrectomy during the same period. The operation was performed by one of two senior surgeons. Total and distal subtotal gastrectomy were performed in 63 and 100 patients respectively. Lymphadenectomy included only the perigastric nodes in 105 patients (64·4 per cent) and some n2 nodes, with staging intent, in 58 (35·6 per cent).

Tumour location and gross appearance, histological type according to Laurén, margins of clearance in the resection specimen, depth of invasion and regional lymph node involvement were recorded.

Among patients undergoing extended lymphadenectomy, resection was judged to be 'absolutely curative' ($H_0 P_0 S_{0-2} N^+ < R$ according to Japanese nomenclature) in 122 cases and 'relatively curative' ($H_0 P_0 S_{0-2} N^+ = R$) in 13 cases. Eight patients underwent 'relatively non-curative' resection and 14 'absolutely non-curative' resection.

Among patients undergoing limited lymph node dissection, tumour resection was judged to be curative in 128 cases when no grossly visible tumour tissue (metastatic and/or lymph node involvement) had been left and resection margins were histologically free from disease. Some 35 patients therefore underwent palliative resection.

The length of operation, intraoperative blood loss, postoperative morbidity rate, hospital mortality rate and 5-year survival after curative resection were recorded in both groups.

Statistical analysis

Statistical analysis was carried out using the BMDP package (BMDP Statistical Software, Los Angeles, California, USA). Results are expressed as mean(s.d.). The significance of differences between means was assessed using Student's *t* test and comparison of the rate of occurrence of events using Fisher's exact test. Survival curves were constructed according to the actuarial life-table method. Only patients undergoing curative resection were included, after exclusion of operative deaths. Therefore, survival after curative resection was studied in 238 patients: 117 after extensive and 121 after limited lymph node dissection. Nine patients (3·8 per cent) were lost to follow-up: five (4·3 per cent) of those undergoing extended lymphadenectomy and four (3·3 per cent) of those undergoing limited dissection.

A total of 146 patients (61·3 per cent) were followed for 5 years after operation. Survival curves were compared using the Mantel–Cox test[9].

analysis were entered into a multivariate model. Multivariate analysis was applied using the Cox regression proportional hazards model[10].

Results

Age–sex distribution and pathological features were similar in the two groups (*Table 1*). The mean(s.d.) number of lymph nodes dissected per operative specimen was 37·0(22·4) in the patients undergoing extended lymphadenectomy and 12·4(8·9) in those receiving limited dissection ($P = 0·0001$). Histological examination revealed nodal involvement in 93 patients (59·2 per cent) and 105 patients (64·4 per cent) in the extensive and limited dissection groups respectively ($P = 0·2$); there were 56 (35·7 per cent) and 73 (44·8 per cent) with positive n1 nodes, and 18 (11·5 per cent) and 32 (19·6 per cent) with n2 involvement. In 19 patients (12·1 per cent) undergoing extensive dissection n3 nodes were involved.

Morbidity and mortality rates

The mean(s.d.) operating time was 269(82) min for extended lymphadenectomy and 220(78) min for limited dissection ($P = 0·0001$). The mean(s.d.) intraoperative blood transfusion requirement was 578(481) and 438(456) ml respectively ($P = 0·009$). The incidence of postoperative complications

*Fisher's exact test

(*Table 2*) was similar in the two groups (22·3 *versus* 28·2 per cent, $P = 0·13$).

The hospital mortality rate was 3·8 per cent after extensive and 7·4 per cent after limited lymph node dissection ($P = 0·12$).

Survival

The 5-year survival rate after curative resection was 65·4 per cent for extended lymphadenectomy and 50·1 per cent for limited dissection ($P = 0·01$). The rates were 85·9 *versus* 82·2 per cent for stage I disease ($P = 0·60$), 66·1 *versus* 57·8 per cent for stage II ($P = 0·82$), and 48·7 *versus* 29·8 per cent for stage III ($P = 0·02$) (*Figures 1–4*).

When applied to all patients undergoing curative resection, univariate analysis showed that poor survival was closely related to the site of the primary lesion, tumour node metastasis (TNM) stage and the extent of lymphadenectomy. In contrast, no significant differences were found with regard to age, sex, gross tumour appearance, histological type and extent of gastric resection (*Table 3*).

Table 4 *Independent prognostic variables identified by a Cox proportional hazards model using the covariates in* Table 3

Prognostic variable	Hazards ratio	*P**
Lymph node dissection		
Limited *versus* extensive	0·55 (0·35–0·87)	0·01

Values in parentheses are 95 per cent confidence intervals. *Mantel–Cox test

Of the three factors found to be prognostically significant by univariate analysis, the Cox multivariate model confirmed that all three were independent predictors of death from the disease (*Table 4*). Location of the tumour in the upper third of the stomach, progression of disease into the gastric wall and regional lymph nodes, and lymphadenectomy limited to the perigastric nodes were associated with a shorter survival time and higher risk of death from gastric cancer.

Discussion

The need to perform extensive lymph node dissection in the surgical treatment of gastric cancer remains controversial. Many reports have suggested an aggressive procedure ($R_{2/3}$ gastrectomy) based on the assumption that the more extensive removal of lymph nodes permits a more accurate staging and a better prospect of cure[11–13]. However, other investigators have recommended a less aggressive approach. The main argument for R_1 gastrectomy is the much lower postoperative morbidity and mortality rates with no statistically different survival rate when compared with results of extended lymphadenectomy in several reports[7,14].

The aim of the present study was to compare extended lymphadenectomy with limited nodal dissection in the surgical treatment of gastric carcinoma. As far as early postoperative results are concerned, this study confirms that the more extensive dissection leads to a longer operating time and greater blood loss[14]; however, no differences were observed in postoperative morbidity and mortality rates between the two procedures. All the extensive dissection operations were performed by the same senior surgeon: this might explain the lower than expected incidence of postoperative complications in this group of patients. Nevertheless, the results suggest that extended lymphadenectomy, when performed in a standardized manner, does not significantly increase complication and mortality rates compared with limited dissection.

Long-term results after curative resection show the survival advantage of extensive over limited lymphadenectomy, a difference that was more marked when patients with stage III disease were considered separately. It must be underlined that lymph node involvement might be underestimated in patients undergoing limited dissection in comparison with those receiving extended lymphadenectomy, because of the presence of undetected n3 metastases. This possibility does not affect the overall finding of reduced survival in patients who underwent limited dissection, as it is reasonable to assume that more extensive lymphadenectomy might have resulted in surgical cure of some patients with undetected micrometastases in those undergoing limited dissection.

Multivariate analysis using the Cox model confirmed the extent of lymphadenectomy as an independent predictor of survival in patients undergoing curative resection. Statistical analysis showed that, even though there are predetermined factors that govern survival, such as location of the tumour and TNM stage, the surgeon's choice and manner of execution of surgery can have a significant effect on prognosis.

In conclusion, despite the unfavourable results of previous Western studies comparing extensive with limited lymph node dissection, the present data clearly show the safety and efficacy of extended lymphadenectomy in the surgical treatment of gastric cancer. The results are in agreement not only with those of Japanese authors but also with reports of $R_{2/3}$ gastrectomy recently performed outside Japan[15–17] and support the efficacy of extended lymph node dissection in the surgical management of gastric carcinoma.

Small bowel prolapse and incarceration caused by a vaginal ring pessary

R. Ott, H. Richter, J. Behr* and J. Scheele

*Departments of Surgery, and *Obstetrics and Gynaecology, University Hospital, Maximiliansplatz 1, D-91 054 Erlangen, Germany*

Correspondence to: Dr R. Ott

Incarceration of the intestine is always a surgical emergency. Most frequently, it occurs into external or internal hernias. An unusual case of small bowel incarceration into a vaginal ring pessary is reported.

Case report

A 72-year-old woman was seen in the emergency room with a 2-h history of acute abdominal pain and transvaginal prolapse of the bowel, which had developed immediately after a strong fit of coughing. The patient had undergone transvaginal hysterectomy and colpoperineoplasty 10 years previously for vaginouterine prolapse. A soft rubber vaginal ring pessary of 5·5 cm diameter had been inserted 5 years later because the woman had developed a recurrent rectocystocele but had refused further operation. Periodic follow-up examinations had always been unremarkable.

On clinical examination bowel loops were visible, protruding externally from the vagina (*Figure 1*). The blood pressure was 200/130 mmHg and the heart rate 88 beats/min. The abdomen was tender with no guarding and bowel sounds were decreased. The white blood cell count was slightly raised at $12 \cdot 5 \times 10^9$/l. Plain abdominal radiography showed distended small bowel loops but no air–fluid levels.

At emergency laparotomy, exploration of the pelvis revealed perforation of the vaginal stump and incarceration of the terminal ileum into the vaginal pessary. A 45-cm segment of ischaemic bowel was removed, and end-to-end ileoileal anastomosis performed. The vagina was stabilized by fixation to remnants of the sacrouterine and round ligaments, and the vaginal defect was closed.

The patient had an uneventful postoperative course and was discharged on day 11.

Discussion

There is agreement that definitive treatment of genital prolapse should consist of extirpative or reconstructive surgery, because this is well tolerated even in elderly patients[1]. Vaginal supportive devices should be restricted to patients who refuse or are awaiting operation, since their use is frequently associated with ulceration of the mucous membrane, vaginal discharge and pruritus[2]. Incarceration or perforation of the cervix or parts of the bladder are rare complications that result mainly from neglect[1].

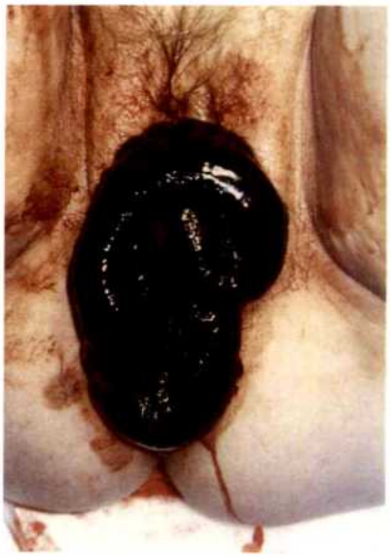

Figure 1 *Transvaginal bowel prolapse*

Intestinal obstruction caused by a vaginal pessary is a clinical rarity. A literature review of this complication revealed two reports of compression ileus but not a single instance of incarceration and transvaginal bowel prolapse. Seling and Lindenfelser[3] described a patient in whom a retrovaginal small bowel loop was compressed by a ring pessary; a similar case was reported by Lukowski[4]. In the present patient, intestinal obstruction and bowel prolapse resulted from perforation of the vaginal stump and incarceration into the ring of the pessary. This was clearly related to the preceding hysterectomy, since the uterus with its fixation in the pelvis acts as a barrier between the abdominal cavity and vagina.

Factors associated with early discharge after inguinal hernia repair in 500 consecutive unselected patients

B. Millat, A. Fingerhut, M. Gignoux, J.-M. Hay and the French Associations for Surgical Research

Association de Recherche en Chirurgie and Association Universitaire de Recherche en Chirurgie, Bois-Colombes, France

Dr B. Millat, Service de Chirurgie A, Hôpital Lapeyronie, 555 Route de Ganges, 34 059 Montpellier, France

The feasibility of discharge within 48 h of surgery was evaluated in 500 consecutive men with unilateral uncomplicated non-recurrent inguinal hernia. Fifty-nine patients were unsuitable for short-stay surgery on medical or social grounds. Of 411 patients suitable for early discharge, 107 stayed longer than 48 h. Early discharge was declined by 84 otherwise suitable patients and contraindicated because of local or general complications in 42. A total of 304 patients were discharged within 48 h; 1-day surgery was performed in 51 patients. Employment, low physical requirements, a lower age and fewer than two medical risk factors were associated with feasible and successful short-stay surgery. These factors may not be independent variables.

The feasibility of early discharge from hospital after inguinal hernia repair in selected patients was established 30 years ago[1]. The question remains of how to select patients for early discharge, particularly when financial incentives are not likely to promote acceptance[2]. Accurate prediction of the delay to discharge might optimize the use of hospital beds. The present study was conducted to determine the relative predictive values of medical fitness, social support and patient acceptance in the feasibility of early discharge after inguinal hernia repair. The objective was discharge within 48 h of surgery.

Patients and methods

Over an 18-month period, 500 consecutive male patients aged 16 years or over were seen in the outpatient departments of 17 surgical centres of two French associations for surgical research. All hernias were inguinal, unilateral, uncomplicated and non-recurrent. At the initial interview, based on the referral letter from the general practitioner and/or information from the patient concerning medical history and social conditions, the consultant surgeon decided whether the patient was suitable for short-stay surgery. Social and medical assessment variables are shown in *Table 1*. Suitable patients were asked to stay 48 h or less after surgery; they could accept or decline this proposition.

The surgical team chose the type of anaesthesia and method of repair. Each patient was assessed from surgery until discharge with particular reference to the wound, and possible local and general complications. The date of discharge and reason for any delay beyond the proposed postoperative stay were recorded. An outpatient visit after 1 month was used to assess late complications.

Table 1 *Social and medical variables used in assessment*

Social
- Employment*
- Distance from home to hospital
- Housing conditions (poor accommodation, inadequate domestic support)
- General practitioner
- Availability of home nurse care

Medical (score 1 for each)
- Chronic respiratory disease
- Smoking more than ten cigarettes per day
- Chronic constipation
- Dysuria
- Anticoagulant therapy
- Other associated medical or surgical conditions

*Graded according to physical requirements from 1 (sedentary work) to 4 (heavy physical work)

Comparisons between group means were made using Student's t test; χ^2 with Yates' correction or Fisher's exact test, as appropriate, were used for evaluation of qualitative variables.

Results

The results are summarized in *Figure 1*. Delayed discharge was anticipated on medical or social grounds and/or because of patient refusal in 89 patients (18 per cent). Details of 411 patients of mean(s.e.m.) age 54(15) (range 16–89) years admitted for short-stay surgery are given in *Table 2* and postoperative complications in *Table 3*. In total, 107 patients remained in hospital for more than 48 h. Early discharge was refused by 103 patients either before ($n = 42$) or after ($n = 61$) operation; patient refusal was the single reason for delayed discharge in 30 patients before and in 54 after operation. A total of 56 local and 24 general complications were diagnosed while the patients were in hospital, delaying discharge in 42 patients. Local complications did not occur significantly more frequently after local anaesthesia (29 of 229; 13 per cent) than after epidural or general anaesthesia (27 of 182; 15 per cent). On the other hand, general complications were more frequent after epidural or general anaesthesia (16 of 182 *versus* eight of 229; $P < 0\cdot05$).

Factors associated with the feasibility and success of short-stay surgery are given in *Table 4*. Only the medical risk score differed between the patients with delayed discharge and those for whom early discharge was not feasible. Having no general practitioner was associated with a lower medical risk ($P < 0\cdot02$); of 66 patients without a practitioner, 47 had no medical risk factors and 19 had only one. Of 304 patients discharged, 165 (54 per cent) were operated on under local anaesthesia, as were 64 of 107 (60 per cent) with delayed discharge (P not significant). Age and employment were not independent variables: mean(s.d.) age was no different when employed patients discharged within 48 h ($n = 201$) were compared with those with delayed discharge ($n = 45$) at 45(11) *versus* 46(11) years respectively. In unemployed patients, however, lower age was associated with early discharge

($n = 103$) compared with those with declined or delayed discharge ($n = 62$): mean(s.d.) 60(15) *versus* 70(14) years respectively ($P < 0{\cdot}001$). In the overall population lower age was associated with early discharge only in patients with a medical risk score <2 (*Table 5*).

Fifty-one patients were discharged the evening after operation (defined as discharge on day 0 or ambulatory surgery). Factors associated with ambulatory surgery are reported in *Table 6*.

The predictive values of factors associated with early discharge are reported in *Table 7*. The most accurate prediction of early discharge was achieved in the group of employed patients with low physical requirements. These criteria detected only 134 of 304 patients (44 per cent) accepting and going on to receive short-stay surgery.

Housing conditions, distance from home to hospital and availability of home nurse care were not discriminant factors in any of the groups compared.

Discussion

Given certain medical and/or social prerequisites, short hospital stay for hernia repair is technically feasible and medically safe[1,3-5]. Acceptance of this policy is dependent on the patient in social systems of reimbursement for hospital care where direct costs are not conducive to promoting acceptance[2]. Patient acceptance and the medical decision had the same weight in determining the feasibility of short-stay surgery in the present study. Accurate prediction of the delay to discharge is necessary to optimize the use of hospital beds, particularly when day-case surgery is performed in centres without day-bed units. As earlier series referred to preselected patients, the definition of factors associated with this prediction was missing. Factors such as domestic support and medical services[6], chronic respiratory disease[7], chronic cough and bladder outflow obstruction[8] have been identified as important variables but employment has never been evaluated. Professional physical requirements influenced the success of short-stay surgery in the present study. The importance of the work variable was underestimated before surgery by consultant surgeons, who paradoxically anticipated short-stay surgery more often in the group with high physical employment requirements (*Table 7*). The 61 per cent rate of patients leaving hospital within 48 h of operation compares favourably with that of 23 per cent reported by Cannon *et al.*[6].

In the present study local anaesthesia was associated with successful ambulatory surgery (*Table 6*). As the technique of anaesthesia was not randomized, it was not possible to determine a causal relationship. The indication of local anaesthesia might refer, in the minds of the patient and/or surgeon, to an acceptance of, or a motivation for, early discharge. Local, epidural and general anaesthesia for standard inguinal herniorrhaphy have already been compared in a randomized controlled trial[9]; there were no significant differences in the groups. In the present study general complications occurred more frequently after epidural or general anaesthesia ($P < 0{\cdot}05$) and contraindicated early discharge in 21 patients (*Table 4*). Local complications were not related to the type of anaesthesia. Of the 56 patients with local complications, 28 had a delayed discharge (*Table 4*), underlining the importance of surgical skill in successful short-stay surgery. These results were obtained in surgical centres without structured day-care units. The study provides an objective basis for investment in such units and for the evaluation of their efficiency.

A retrospective study was made of 34 patients who underwent major liver resection with a single period of vascular occlusion exceeding 60 min. The liver remnant was normal in all cases. Vascular occlusion was achieved by continuous portal triad clamping (15 patients), hepatic vascular exclusion (15) or a sequential combination of both procedures (four). Liver cooling was not used. The mean(s.e.m.) duration of continuous normothermic liver ischaemia was 73·6(2·5) (range 60–127) min. The mean(s.e.m.) amount of blood transfused during operation was 5·3(0·8) units packed red cells. There were no deaths after surgery and the postoperative course was uneventful, or limited to asymptomatic pleural effusion, in 18 patients. Three patients suffered postoperative bleeding necessitating further surgery and one of these required reintervention for a prolonged bile leak. Four patients had transient liver failure that resolved spontaneously within 15 days. There was a 13-fold increase in serum transaminase activities and the proaccelerin level was 45 per cent that of normal on day 1 after operation. These changes were returning to normal levels within 15 days. Continuous vascular occlusion during major liver resection is a useful manoeuvre that may be performed safely on normal hepatic parenchyma for up to 90 min.

Temporary vascular occlusion has been proposed as a technique to decrease bleeding during liver surgery[1,2]. This reduction is desirable as the amount of blood transfused during operation has a major bearing on the postoperative course[1–3].

In the early 1960s it was believed that the human liver tolerated normothermic ischaemia poorly and that temporary portal triad clamping for >15 min was hazardous[4]. This principle has been challenged by studies from the authors' department[1,5,6] and other centres[2,7–10], and it is now accepted that hepatic vascular occlusion may be performed for up to 60 min without major detrimental effects.

Advances in the field of liver surgery towards more complex and extensive hepatic resection have raised the need for longer periods of vascular occlusion. Nevertheless the maximal advisable duration of vascular clamping and consequent liver ischaemia in humans remains unknown.

To determine the effects of prolonged continuous normothermic ischaemia on liver parenchyma, the clinical records of 34 patients who underwent hepatectomy performed with a single period of vascular occlusion exceeding 60 min were reviewed retrospectively. Tolerance of the liver to prolonged normothermic ischaemia was assessed by analysis of the postoperative outcome and biochemical changes.

Patients and methods

Patients

Between January 1981 and July 1991, 459 patients underwent liver resection in the authors' department, and a review was made of 34 (7·4 per cent) of these in whom hepatectomy had been performed with a single period of vascular occlusion lasting ≥60 min. All 34 patients had tumours in an otherwise healthy liver. Patients with cirrhosis, or fatty or cholestatic changes of the liver remnant were excluded.

There were 11 women and 23 men, with a mean(s.e.m.) age of 54(2) (range 34–75) years. According to the American Society of Anesthesiologists' classification[11], 21 patients were grade I, 11 were grade II and two were grade III. The indication for resection was secondary liver tumour in 26 patients and benign disease in eight (*Table 1*).

Preoperative management

For patients with malignant disease, preoperative investigation included physical examination, chest radiography and endoscopy, when appropriate, to exclude extrahepatic disease. Thoracic computed tomography was performed on patients later in the series. Preoperative blood investigations included coagulation tests (prothrombin and proaccelerin levels), and estimation of serum alanine transaminase (ALT) and asparate transaminase (AST), bilirubin, serum alkaline phosphatase, creatinine, albumin and total protein.

Surgical technique

Operative procedure. The abdomen was opened through a bilateral subcostal incision. In three patients a thoracic extension was necessary, either because of suspected involvement of the hepatocaval confluence or because of the existence of a large posterior tumour. The liver was mobilized by division of its ligaments. Dissection of the inferior vena cava below and above the liver was performed if hepatic vascular exclusion was already planned, but was postponed in other cases. The

planned limits of resection were first marked on Glisson's capsule using diathermy coagulation, and after vascular occlusion (see below) liver transection was performed by crushing the hepatic tissue with a pair of artery forceps. The delineated branches of the vascular and biliary system thus isolated were divided between metal clips or ligatures. At the end of the procedure the portal pedicle and hepatic vein were transected using a vascular stapling device. This intraparenchymal approach without prior ligation of the hilar vessels or hepatic veins was considered the safest procedure in relation to possible anatomical abnormalities. All 34 patients underwent major hepatectomy, i.e. resection of at least three segments according to Couinaud[12] (*Table 1*). At the end of the procedure, the hepatic fossa was drained with two large-bore silicone drains brought out through separate stab incisions in the right abdominal wall.

Vascular control. All 34 liver resections were performed with temporary vascular occlusion to reduce intraoperative bleeding. Occlusion was applied continuously without intermittent release of the vascular clamps. Liver cooling such as topical refrigeration or hypothermic perfusion was not used. Vascular occlusion was performed by continuous portal triad clamping, the Pringle manoeuvre[13], in 15 patients. In a further 15 patients hepatic vascular exclusion, i.e. portal triad clamping as well as occlusion of the inferior vena cava below and above the liver[5,14], was performed during resection. The exclusion technique was indicated for resection of large hypervascular or posterior tumours located close to the vena cava or hepatic veins, which carry a high risk of haemorrhage or air embolism during hepatectomy. In four patients both manoeuvres were performed sequentially; in two clamping of the inferior vena cava in addition to portal triad clamping was necessary because of uncontrolled bleeding from a hepatic vein during liver transection. Two other patients in whom major resection was performed using hepatic vascular exclusion subsequently underwent a further non-anatomical resection from the liver remnant using portal triad clamping alone after release of the caval clamps.

Intraoperative temperature control

Throughout the study period, warming therapy was applied to minimize intraoperative hypothermia. Measures used included body insulation, inspiratory gas and liquid replacement heating, a circulating water mattress and, since 1987, leg warming by a heating blanket. Intraoperative core temperature was measured using a thermistor placed in a Swan–Ganz catheter.

Postoperative management

After operation patients were transferred to the intensive care unit. They had daily clinical examinations, including screening for evidence of encephalopathy. A coagulation profile was performed on the evening of operation and full blood chemistry daily during the first week and then twice weekly until discharge from hospital.

Antibiotic prophylaxis consisted of administration of a β-lactam drug for 48–72 h in association with an aminoglycoside and metronidazole. No anticoagulant therapy was used in the immediate postoperative period.

Statistical analysis

Deaths that occurred within 30 days of hepatectomy, and those during the initial hospitalization for liver resection, were included in the operative mortality data. The length of stay in the intensive care unit and in hospital after operation was recorded.

Several factors were analysed to determine their correlation with the postoperative course: weight of resected specimen, type of vascular occlusion, amount of blood transfused during surgery, duration of liver ischaemia and intraoperative core temperature.

Results are expressed as mean(s.e.m.). Differences between groups were tested with analysis of variance and Fisher's test for least significant difference. The χ^2 test, with Yates' correction when appropriate, was used to determine the significance of differences in the frequency of variables between groups. Correlation was evaluated by standard linear regression. Statistical analysis was carried out using a standard biomedical program (Statview II; Abacus Concepts, Berkeley, California, USA). $P < 0{\cdot}05$ was considered significant.

Results

Operative mortality

There were no intraoperative or postoperative deaths.

Postoperative morbidity

In 18 of the 34 patients the postoperative course was either uneventful or marked by asymptomatic mild pleural effusion (eight patients). Three patients required reoperation for postoperative bleeding following left hepatectomy (one patient), right hepatectomy (one) and extended right hepatectomy with partial resection of segments II and III (one). The duration of liver ischaemia for these patients was 60, 70 and 127 min respectively. The last patient had to undergo surgery again on the 15th day after operation for a bile leak. Four patients suffered transient liver failure with mild encephalopathy and ascites following right (two patients) and extended right (two) hepatectomy performed with vascular occlusion lasting for 70, 80, 85 and 90 min. The ascites resolved spontaneously within 15 days in all four cases. Other complications included pulmonary embolism (two patients), pneumonia or atelectasis (seven), wound infection (two) and cardiac arrhythmia (one). The mean(s.e.m.) lengths of stay in the intensive care unit and in hospital were 6·4(0·9) (range 1–25) and 17·6(1·5) (range 7–42) days respectively. The incidence of postoperative complications correlated significantly with stay in intensive care ($F = 10{\cdot}04$, $P = 0{\cdot}003$) and in hospital ($F = 19{\cdot}93$, $P = 0{\cdot}0001$).

Intraoperative management

The mean(s.e.m.) duration of continuous vascular occlusion and of the surgical procedure was 73·6(2·5) and 390(140) min. In one case, vascular occlusion was extended to 127 min because of a technically difficult hepatectomy. The mean(s.e.m.) core temperature during liver ischaemia was 35·0(0·2) (range 32·7–37·4)°C. It was 35·1(0·3) (range 32·1–37·1)°C at the end of the procedure after the abdomen had been closed and the patient transferred to the recovery room. The mean(s.e.m.) intraoperative blood transfusion was 5·3(0·8) (range 0–19) units packed red cells. For the last 23 patients in the series, operated on between 1987 and 1991, the amount of blood transfused had reduced to a mean(s.e.m.) of 2·6(1·8) (range 0–6) units. Six patients were not transfused. *Table 2* summarizes the relationships between the duration of liver ischaemia and parameters observed during and after resection. The amount of blood transfused and the length of stay in intensive care correlated positively with the duration of liver ischaemia. Monitoring of expired carbon dioxide and pulmonary artery pressure revealed no evidence of air embolism.

Liver function

Postoperative changes in the levels of serum transaminases, bilirubin and in coagulation are shown in *Table 3*. There was a 13-fold rise in transaminase levels on day 1. By day 7 ALT and AST levels had fallen to fivefold and twofold of their preoperative value. No correlation was found between the level of transaminases on day 1 and the duration of liver ischaemia (*Table 2*). There was a fall in prothrombin and proaccelerin levels on day 1 to 48 and 45 per cent of normal values respectively. These values were >60 per cent of normal by day 3 in 25 patients. The proaccelerin level on day 1 did not correlate with the duration of liver ischaemia (*Table 2*).

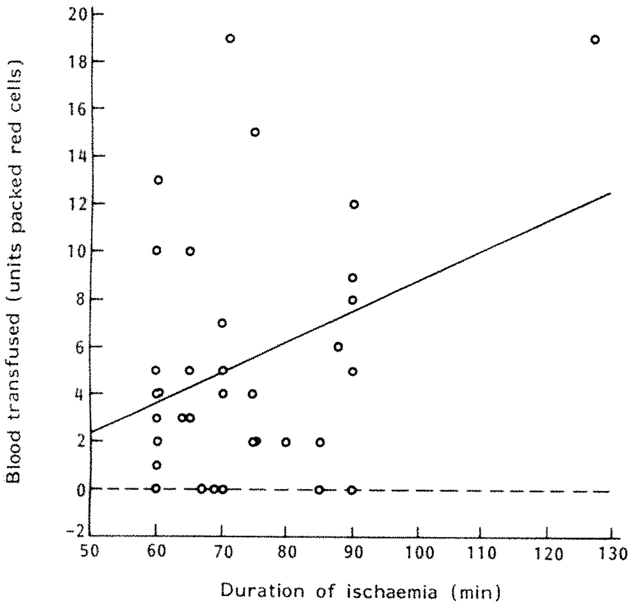

Figure 1 *Relationship between the duration of liver ischaemia and the amount of blood transfused.* r = *0·45*, P = *0·008*

Factors affecting morbidity

Amount of blood transfused. Although the amount of blood transfused during surgery correlated with the length of stay in the intensive care unit ($r = 0{\cdot}52$, $P = 0{\cdot}002$) and in hospital ($r = 0{\cdot}51$, $P = 0{\cdot}002$), the relationship between transfusion and the incidence of postoperative complications was not significant ($F = 1{\cdot}48$, $P = 0{\cdot}2$).

Weight of resected specimen. For all 34 patients, the mean(s.e.m.) weight of the resected specimen was 1010(94) g. The lengths of intensive care and hospital stay were related to the weight of the liver specimen ($r = 0{\cdot}46$, $P = 0{\cdot}006$; $r = 0{\cdot}47$, $P = 0{\cdot}005$ respectively). There was a significant correlation between the weight of the resected specimen and the occurrence of postoperative complications ($F = 4{\cdot}9$, $P = 0{\cdot}03$), but no relationship was found between the weight of the specimen and intraoperative blood loss.

Duration of liver ischaemia. There was no correlation between the duration of hepatic ischaemia and the occurrence of postoperative liver failure ($F = 1{\cdot}3$, $P = 0{\cdot}26$) or complications ($F = 0{\cdot}001$, $P = 0{\cdot}98$). The duration of ischaemia correlated with the amount of blood transfused ($r = 0{\cdot}45$, $P = 0{\cdot}008$) (*Figure 1*) and the length of stay in intensive care ($r = 0{\cdot}36$, $P = 0{\cdot}04$) (*Figure 2*) but not with the duration of stay in hospital (*Table 2*). Two groups of patients were compared: those in whom the duration of liver ischaemia was <75 min (mean(s.e.m.) 64·3(1·0) (range 60–74) min; $n = 20$) and those in whom the duration was ⩾75 min (mean(s.e.m.) 86·8(3·5) (range 75–127) min; $n = 14$) (*Table 4*). No difference was noted between the two groups with regard to the incidence of liver failure, postoperative complications, the amount of blood transfused, or length of stay in the intensive care unit or hospital.

Type of vascular control. When comparing patients undergoing liver resection with portal triad clamping alone (15) with those operated on with hepatic vascular exclusion alone (15), no significant difference in the postoperative course was found (*Table 5*). The only significant difference in intraoperative measurements was a lower mean core temperature during ischaemia in patients undergoing vascular exclusion.

Core temperature during liver ischaemia

Patients in whom the core temperature during vascular occlusion was <35°C (mean(s.e.m.) 34·1(0·2)°C; $n = 17$) were compared with those in whom it was ⩾35°C (mean(s.e.m.) 36·0(0·2)°C; $n = 17$). No significant difference was noted between the groups regarding the extent of hepatectomy, weight of the resected specimen ($P = 0{\cdot}10$) or the duration of vascular occlusion ($P = 0{\cdot}42$). Postoperative biochemical changes in patients with mean core temperature <35°C or ⩾35°C were not significantly different on day 1 (mean(s.e.m.) AST 389(63) and 424(79) units/l, $P = 0{\cdot}36$; ALT 387(41) and 511(141) units/l, $P = 0{\cdot}22$; proaccelerin 45(3) and 45(4) per cent,

Discussion

More than 80 years after the first report of portal triad clamping by Pringle[13] in 1908, temporary occlusion of the blood supply to the liver is widely accepted as an efficient manoeuvre to decrease bleeding during liver surgery. Moreover, it has been shown that intraoperative bleeding is a major prognostic factor[1–3] and that the use of vascular clamping reduces the amount of blood transfused during liver resection[2].

Although the maximal advisable duration of normothermic liver ischaemia has dramatically increased in recent years, the upper limit remains unknown. The fear of adverse effects associated with prolonged warm liver ischaemia and the need for longer periods of vascular clamping have led to the revival of surgical procedures such as *in situ*[15] or *ex situ*[16,17] hypothermic hepatic perfusion. These approaches, introduced by Fortner *et al.*[15], have been used when a technically challenging hepatectomy was foreseen. With the use of hypothermic perfusion, major liver resection (often including vascular reconstruction) has been performed with periods of vascular occlusion[15–17] extending up to 9 h. The question remains whether hypothermic perfusion has any benefit for shorter periods of vascular occlusion, i.e. when clamping for >60 min is expected.

Since the beginning of the 1980s a policy of continuous vascular occlusion during liver surgery, mainly through the development of hepatic vascular exclusion, has been adopted in the authors' department. In the present series of 34 major liver resections with a single period of vascular occlusion >60 min, hospital mortality was nil and the postoperative course was uneventful in >50 per cent of patients. For the larger and more complex resections, the mean amount of blood transfused during operation was only 5·3 units packed red cells. Improvements in surgical technique and meticulous attention to haemostasis reduced the mean transfusion rate to 2·6 units packed cells per patient during the last 5 years of the study period, including six patients who underwent major liver resection without blood transfusion. Despite this reduction in blood requirement, there is still a correlation between intraoperative blood transfusion and the length of intensive care and hospital stay, confirming the importance of transfusion in the postoperative course in liver surgery.

The present study confirms the tolerance of liver cells to prolonged normothermic ischaemia. Liver failure was rarely encountered and was always mild and transient. Furthermore, neither the incidence of liver failure nor the occurrence of postoperative complications was related to the duration of hepatic ischaemia. Changes in serum liver enzyme levels were always transient with a trend returning towards the preoperative level within the first week. Unlike other reports[7], but in agreement with the authors' previous results[1] and those of Huguet *et al.*[10], no correlation was found between postoperative transaminase levels and the duration of ischaemia. Indeed, liver ischaemia is not the only factor responsible for release of transaminases. Surgical trauma probably contributes considerably to this, as suggested by the eightfold increase in serum levels of transaminases seen after hepatectomy performed with no vascular occlusion[3]. Again, the serum level of proaccelerin on day 1 did not correlate with the duration of ischaemia, whereas it was significantly related to the weight of the resected specimen. Thus, the biochemical changes after liver resection with prolonged normothermic ischaemia appear impressive but transient.

It has been advocated[5] that moderate hypothermia during liver resection might improve the tolerance of liver cells to prolonged ischaemia. The present results do not support this hypothesis: the postoperative changes in biochemical liver test results were similar in patients regardless of the core temperature during ischaemia. As intraoperative hypothermia has many documented deleterious effects[18], particularly on haemostasis and blood loss, it seems preferable to use various warming devices to minimize the fall in core temperature during major hepatectomy.

Long-term ischaemia has also been reported[8] with the use of intermittent portal triad clamping for cycles of vascular occlusion of 20 min each, followed by reperfusion of the liver for 5 min. This allows a long duration of liver ischaemia, ranging up to 150 min, with low mortality and morbidity and transient changes in serum liver enzyme levels[8]. However, the authors have used continuous vascular occlusion to perform major liver resection in safe, stable haemodynamic conditions[19] with minimal blood loss. The main advantage of continuous clamping of the porta hepatis is to avoid the bleeding that inevitably occurs during periods of clamp release. Haemorrhagic and hypotensive episodes are more likely to occur following release of the vascular clamps, leading to increased haemodynamic disturbance during the subsequent periods of clamping. Intraoperative hypotension has been associated with an increased risk of recurrence after liver resection for colorectal metastases[20]. Continuous clamping should theoretically reduce operative bleeding and the duration of the surgical procedure. Lastly, intermittent vascular occlusion is not appropriate when the characteristics of the tumour indicate hepatic vascular exclusion. The major point that remains to be determined is whether rewarming of the liver parenchyma during sequential reperfusion cycles contributes to a less favourable tolerance to prolonged ischaemia compared with straightforward clamping.

The authors' current policy is to use continuous vascular occlusion, which enables safe, haemodynamically stable and bloodless liver resection to be performed. Whenever the foreseen complexity of the hepatectomy suggests that vascular occlusion might exceed 120 min, we strongly advocate hepatic vascular exclusion with *in situ* hypothermic perfusion of University of Wisconsin preserving solution[21].

In conclusion, prolonged continuous vascular occlusion appears to be a safe, useful and non-deleterious manoeuvre for major liver resection. Continuous clamping may be applied for up to 90 min in healthy parenchyma.

Dr C. E. Iselin

Cystic neoplasms of the pancreas are rare. They may present as a mucinous (malignant or potentially malignant) tumour or as benign serous cystadenoma. Accurate preoperative diagnosis is therefore essential, as an asymptomatic serous tumour may safely be followed clinically for years, whereas mucinous tumours require aggressive surgery. Thirteen patients with cystadenoma and cystadenocarcinoma of the pancreas were reviewed and how best to improve the rate of preoperative diagnosis was considered. Fine-needle aspiration cytology and computed tomography enable accurate preoperative distinction between mucinous and serous cystic tumours of the pancreas.

Cystadenoma and cystadenocarcinoma of the pancreas account for only 1 per cent of pancreatic neoplasms[1]. Since these tumours are rare, they may be mistaken for pseudocysts. Inadequate or inappropriate treatment, such as cystenterostomy of cystadenocarcinoma, may then be performed[2]. This is unfortunate because cystadenocarcinoma may be cured surgically. The prognosis of such malignant cysts is more favourable than that of the more common solid adenocarcinoma of the pancreas: after total excision, non-metastatic cystadenocarcinoma carries a 10-year survival rate of 70 per cent[3] compared with 30 per cent at 2 years for solid adenocarcinoma[4]. Accurate preoperative diagnosis is therefore essential to allow the correct choice of operative procedure and to enable appropriate treatment of neoplastic pancreatic cysts.

Cystic pancreatic tumours are either serous or mucinous. It is essential to differentiate between these two subtypes, as the former is usually benign whereas the latter is malignant or potentially so[5]. Computed tomography (CT) remains the first-choice diagnostic tool[6]. Percutaneous fine-needle aspiration cytology (FNAC) has recently been used in the diagnosis of these tumours[6], although its role is still under evaluation. The purpose of the present study was to review a series of cystic pancreatic tumours from this institute and other reported results to select CT and FNAC criteria that may lead to more accurate preoperative diagnosis.

Patients and methods

The records of 13 patients who were diagnosed as having a cystic neoplasm of the pancreas were reviewed. Five further patients were diagnosed at autopsy: one 90-year-old woman who died shortly after admission with abdominal distension had metastatic mucinous cystadenocarcinoma of the pancreas and four patients had an incidental cystadenoma diagnosed after death from an unrelated cause.

When the histological diagnosis appeared uncertain, the slides were re-examined by a pathologist. Clinical follow-up was obtained through the patient's personal physician or at outpatient attendance.

Nine of the ten original CT films were available; these were reinterpreted according to accepted radiological criteria[7] by a radiologist unaware of the clinical and histological findings. The radiologist recorded cyst number and size, and the presence of a central scar and malignant invasion. Four patients underwent preoperative FNAC; the aspirates were examined for cytological characteristics, and content of extracellular and intracellular mucin, and intracellular glycogen.

Results

The 13 patients comprised 11 women and two men of mean age 52 years. Four patients had histologically proven mucinous cystadenoma, five mucinous cystadenocarcinoma and four a serous tumour. Details are given in *Table 1*.

Eight patients had symptoms related to the cystic tumour: seven complained chiefly of abdominal pain, five had weight loss and two showed worsening of diabetes. Two further patients had diarrhoea and one suffered from major haematemesis. The tumour was discovered fortuitously in two patients. On physical examination, five patients had a palpable mass. Jaundice was not encountered. The mean tumour diameter was 10 (range 3–18) cm. There was no difference in tumour location between the pancreatic head or tail (*Table 1*).

Abdominal CT and ultrasonography were the main investigations used, except for the first three patients because these techniques were not available at that time. The surgeon was aware of the diagnosis before operation in six of 12 cases (one patient did not undergo surgery). When the nine CT images were reinterpreted, serous and mucinous tumours were correctly identified in six patients (*Table 2*). FNAC was used in four tumours and diagnosed one serous and one mucinous cystadenoma, but was inconclusive in the other two cases (*Table 3*).

Ten partial pancreatic resections were performed: three pancreatoduodenectomies and seven left splenopancreatectomies (*Table 1*). Total pancreatectomy was necessary in three cases: two tumours invaded the whole gland and one pancreatoduodenectomy specimen showed diffuse mucinous dysplasia on peroperative frozen-section histology. An asymptomatic 78-year-old woman (patient 5) did not undergo operation. Subsequent FNAC supported this course of action, as it showed a serous cystadenoma. This patient remains free from symptoms.

Only one patient of the 12 who left hospital developed recurrent disease. This patient remains alive following repeat surgery (*Table 1*).

Discussion

Cystic pancreatic tumours occur predominantly in women[3,8–12]; in the present series, 11 of 13 patients were female. Nine tumours were mucinous, five of these malignant. Clinical symptoms were not characteristic, although some could be related to pancreatic dysfunction in half of the cases, such as worsening of diabetes, diarrhoea and weight loss. There was only one local recurrence, which confirmed that localized cystic pancreatic tumours are

*The first three patients were treated before computed tomography was available

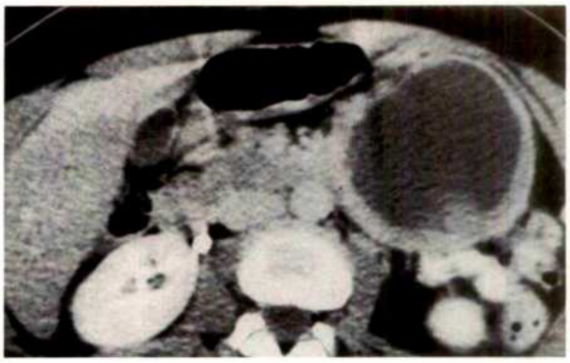

Figure 1 *Mucinous cystadenoma of the tail of the pancreas. The single cyst is large and has a relatively thick wall; there is a papillary proliferation on the inner posterior border. Note that there is no local invasion*

curable provided that there is no malignant dissemination at operation[10]. The absence of metastases at presentation explains the present high survival rate (92 per cent after median follow-up of 8 years), which is slightly higher than usually reported[3,6,8,9,11,13].

The present low rate of correct diagnosis before operation, which is shared by others[2], led to the review of preoperative investigation of these patients. All authors agree that CT is the most important initial procedure[6,7,14,15]. It indicates the size and number of cysts, which are cardinal parameters: mucinous tumours usually have a small number of large cysts whereas serous lesions typically have many small cysts. Johnson *et al.*[7] reviewed CT of 35 pancreatic cystic neoplasms and correctly distinguished mucinous from serous tumours in over 90 per cent of cases. Of the four criteria defined in that study, two were usually diagnostic. With a cyst diameter >2 cm and six or fewer cysts, a mucinous tumour is most probable (*Figure 1*). On the other hand, if the cyst diameter is ≤2 cm and there are more than six of them, a serous tumour is highly likely (*Figure 2*). These morphological features of serous adenoma correspond to the honeycomb or alveolar appearance on CT[11,16], which represents enhancement of the cyst walls after injection of intravenous contrast. The other parameters described by Johnson *et al.*[7] are of less importance: a central scar is suggestive of a serous tumour whereas local tumour invasion suggests cystadenocarcinoma.

Table 3 *Cytological appearance and diagnostic prediction from fine-needle aspiration cytology*

Patient no.	Malignant cytology	Mucin coloration	Glycogen coloration	Amylase level (units l^{-1})	Prediction
5	No	No	Yes	Not measured	Correct
6	No	Not performed	Not performed	Not measured	Inconclusive
8	No	Not performed	Not performed	75000	Inconclusive
13	No	Yes	No	Not measured	Correct

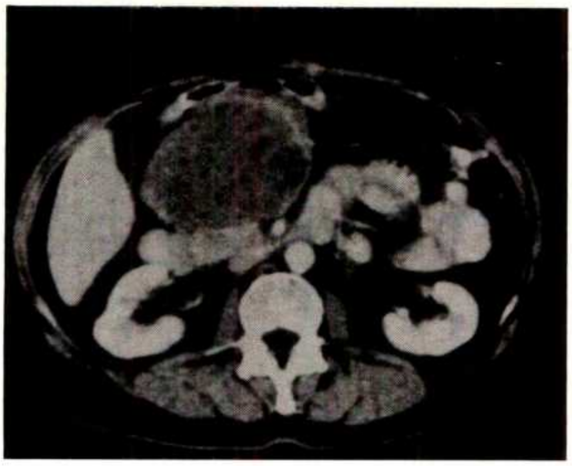

Figure 2 *Serous cystadenoma of the head of the pancreas. The typical honeycomb appearance of these numerous microcysts is best seen after contrast enhancement and with thin (<5 mm) slices*

When the present CT images were reinterpreted according to these criteria, the results were less successful than those of Johnson *et al.*[7], with correct identification in only two-thirds of the present cases (*Table 2*). The experience with preoperative FNAC was therefore re-examined to assess the additional contribution this technique could offer.

FNAC was rarely performed in this institute before 1987. Since then it has been observed that mucin is a reliable cytological feature of mucinous pancreatic tumours[12,17–24]. The diagnosis was made in this way in patient 13 (*Table 3*). Detection of mucin is technically simple and may be performed during operation[6]. Serous tumours can be reliably identified by high intracellular content of glycogen[19,23–25].

All the present FNAC specimens were examined using conventional cytology. The false-negative result in patient 6 could be caused by the characteristically scattered distribution of malignancy in pancreatic cystadenocarcinoma. Two other groups[26,27] claimed a comparable accuracy of cytology with two-thirds of diagnoses confirmed (six of nine patients). Conventional cytology is also useful to exclude the diagnosis of inflammatory pseudocyst, which has no epithelial cells[18,27].

Carcinoembryonic antigen in cyst fluid was not assayed in the present study, although some authors have found high levels in cystadenocarcinoma[17,21,27–29]. This technique may be useful when cystadenocarcinoma is suspected.

FNAC appears to be valuable in preoperative diagnosis but there are two problems with this technique. First, the aspirated material is not always sufficient to allow diagnosis[28,29]; nevertheless, the specificity is 100 per cent and the sensitivity 80 per cent. Second, some cases of needle-track seeding have been reported, a complication that usually occurs after biopsy performed with large-bore needles[30].

The criteria that enable distinction between mucinous and serous tumours are summarized in *Figure 3*. The presence or absence of mucin is a cardinal feature that is usually diagnostic if other criteria are difficult to interpret.

If the tumour is mucinous, radical surgery is the only curative solution. There may be a contraindication to surgery in some cases, such as involvement of major vessels, and palliative internal drainage may be indicated for digestive tract obstruction or obstructive jaundice.

If the tumour is serous, and therefore not life-threatening, the type of surgery depends on the patient's general condition. If there is no contraindication to general anaesthesia any serous tumour should be resected as this leaves no doubt about the final diagnosis. In a patient with relative contraindications to anaesthesia only symptomatic tumours should be operated on[31]. Those located in the body and tail may usually be completely resected as left pancreatectomy is a well tolerated procedure. By contrast, there is no indication for radical resection of cystadenoma in the pancreatic head of a high-risk patient as the operative morbidity rate accompanying pancreatoduodenectomy is high. In such cases, the authors now favour palliative internal drainage. This approach might have been better for patient 7, who died from septic complications after pancreatoduodenectomy (*Table 1*). The recent report of a unique case of malignant serous cystadenocarcinoma[32] emphasizes, however, that non-operated serous cystadenoma requires regular follow-up.

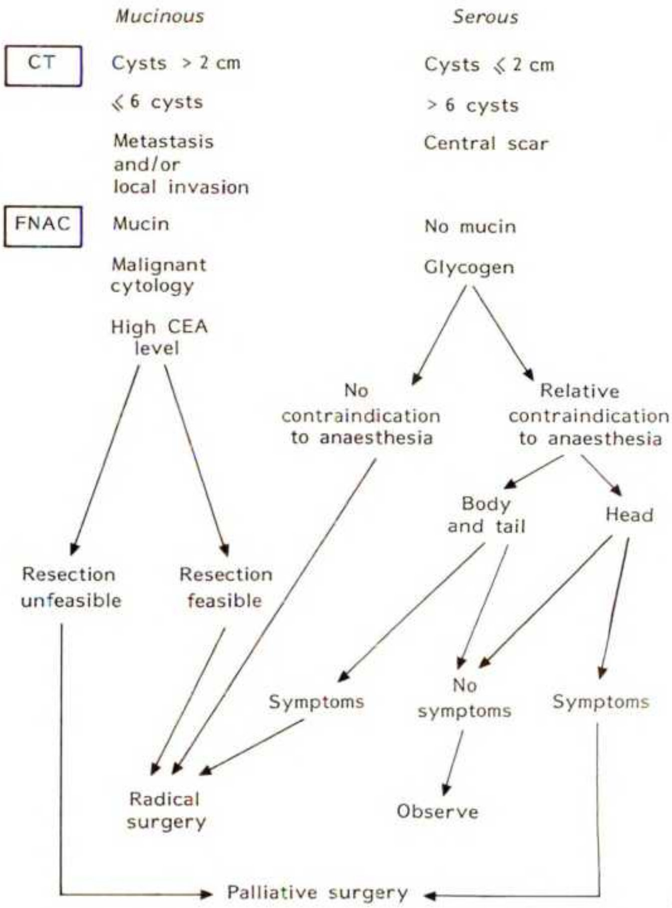

Figure 3 *Preoperative diagnosis and treatment of cystic tumours of the pancreas. FNAC, fine-needle aspiration cytology; CEA, carcinoembryonic antigen*

In conclusion, CT and FNAC used together enable a preoperative diagnosis in most cystic tumours of the pancreas. This may lead to better operative strategy, and may also spare an elderly asymptomatic patient with a serous tumour from a high-risk laparotomy.

Dr M. Büsing, Department of General Surgery, Eberhard Karls University, Tübingen, Hoppe Seyler Straße 3, 7400 Tübingen, Germany

Morphological findings in the initial stages of graft pancreatitis were studied systematically in sequential biopsies of 16 human pancreatic allografts. In 14 patients clinical and morphological signs of graft pancreatitis developed in the early postoperative period. In all cases disturbances in the integrity of structures within acinar cells occurred during ischaemia. In ten cases activation of autophagocytosis occurred following reperfusion, with acceleration of cellular metabolism. After reperfusion a marked leucocyte reaction occurred with a later single acinar cell necrosis in six cases. At the same time, high serum pancreatic enzyme concentrations were observed in all patients following transplantation. Exocrine secretion from the allografts via the pancreatic duct was reduced, correlating with the severity of graft pancreatitis. Studies in this clinical situation might complement analyses of the cascade of morphological and pathophysiological reactions during the early stages of other types of acute pancreatitis.

Few factors involved in the pathogenesis of acute pancreatitis have been defined. It is assumed that uniform cascade-like premature activation of pancreatic proenzymes causes autodigestion of the gland[1–4]. It has been impossible to obtain human pancreatic tissue during the initial stages of the disease, and knowledge of the initial morphological and biochemical changes is based almost exclusively on animal studies. It is difficult to extrapolate these results to the clinical situation[5,6].

Following pancreas transplantation a clinical picture corresponding to acute pancreatitis may develop (graft pancreatitis) and this is ascribed to damage caused by ischaemia and/or preservation of the organ[7–10]. Prospective studies are possible from the onset of graft pancreatitis.

The pathophysiology and morphological changes in the exocrine parenchyma of human pancreas transplants were examined with emphasis on the initial morphological alterations in the biopsy material.

Patients and methods

Thirty-nine combined pancreas–kidney transplantations were performed between January 1987 and November 1990. All patients had diabetes mellitus type I and end-stage renal disease. Most showed further severe secondary diabetic complications.

Removal of the organs from the donors was carried out under stable circulatory conditions. *In situ* perfusion was performed initially with Eurocollins solution, but since August 1988 with University of Wisconsin solution, using a solution kept at 4°C and a balloon catheter in the aorta. Further surface cooling of the pancreas was carried out with iced water. The complete pancreas was removed with the spleen, duodenum and vessels of supply. The organs were continuously cooled at 4°C until reperfusion.

Following prospective negative T cell cross-matches, favourable correspondence of the human leucocyte antigen (HLA) system was used to help select recipients. An incomplete HLA match was not considered a contraindication to transplantation. The whole pancreas with a segment of duodenum was transplanted using the bladder drainage technique[11,12] described by Corry. A side-to-side anastomosis between the duodenal segment and the urinary bladder allowed pancreatic juice to drain into the bladder for excretion in the urine. Three drains were placed next to the pancreas allograft and in the pouch of Douglas, and closed continuous peritoneal lavage carried out with modified peritoneal dialysis solutions (PD11, PD14; Schiwa, Glandorf, Germany) starting 6–12 h after operation. Lavage was performed using mechanical control (APD06; Dialyse Technik, Rheinstetten-Forchheim, Germany) to regulate the volume and frequency (300–500 ml per cycle, 10–15 litres per day). The amylase and lipase content and leucocyte count of the lavage fluid were measured.

Immunosuppressive therapy was started during operation with prednisolone 500 mg and azathioprine 2–3 mg kg^{-1} day^{-1}. After the first postoperative day, cyclosporin A was added to maintain a blood level of 250–300 ng dl^{-1}. In addition, antithymocyte globulin 0·15 ml kg^{-1} day^{-1} was given prophylactically for 10 days. To avoid graft thrombosis, low molecular weight dextran (Thomadex; Thomae, Biberach/Riss, Germany), 250 ml per day for 5 days, and heparin were given intravenously. The heparin dose was adjusted according to the prothrombin time, aiming at a value of 50–60 s during the first 10 days. Later, aspirin, 250 mg per 48 h, was given for long-term anticoagulation. Blood cell count and levels of serum transaminases, amylase, lipase, creatinine and electrolytes, and urine electrolytes and amylase were determined, depending on the clinical situation.

Morphological examination

To assess initial morphological changes, 16 pancreatic grafts transplanted between December 1988 and November 1990 were subjected to serial perioperative biopsy. Tissue samples, measuring approximately 5 × 5 × 5 mm, were taken from the tail of the pancreas immediately before and after cold ischaemia and at 30 min, 90 min and 5–6 h after reperfusion of the graft. Additional specimens were obtained during any reoperations required between 7 and 20 days after transplantation. On removal, tissue samples were immediately fixed in phosphate-buffered 3 per cent glutaraldehyde. The material was further fixed with osmium tetroxide, contrasted *en bloc* in uranyl acetate and embedded in Epon 812 (Fluka, Buchs, Switzerland) for light and transmission electron microscopy. For the purpose of preliminary orientation and light microscopy findings, semithin sections (1·0–1·5 μm) were prepared and stained with methylene blue and basic fuchsine. Ultrathin sections (0·08–0·15 μm) were contrasted in uranyl acetate and lead citrate and examined with a transmission electron microscope (EM 10; Zeiss, Oberkochen, Germany).

Diagnosis of graft pancreatitis

The diagnosis of graft pancreatitis was made following evaluation of clinical symptoms, laboratory findings, the results of ultrasonography and computed tomography, and macroscopic appearance at reoperation.

Results

Organ preservation and duration of graft ischaemia

Eurocollins solution was used in 14 pancreatic–renal transplants for organ preservation. The mean duration of ischaemia was 4 h 50 min (range 2 h 45 min to 6 h 20 min) for

0007-1323/93/091170–04 © 1993 Butterworth–Heinemann Ltd

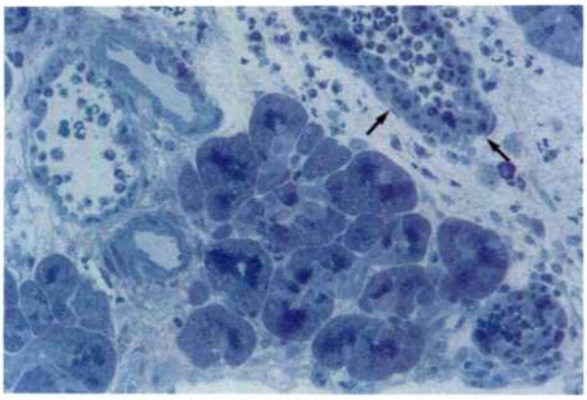

Figure 1 *Leucocyte migration (arrows) between endothelial cells and into the perivascular tissue 90 min after reperfusion. Uneven distribution of zymogen granules within the acinar epithelial cells can be seen. (Basic fuchsine and methylene blue stain, original magnification × 480)*

pancreatic allografts and 7 h 30 min (range 5 h 30 min to 10 h 30 min) for renal allografts. After preservation with University of Wisconsin solution ($n = 25$), the mean duration of ischaemia was 8 h 45 min (range 5 h 30 min to 16 h 00 min) for pancreatic allografts and 12 h 10 min (range 8 h 00 min to 19 h 00 min) for renal allografts.

Initial graft function

Pancreas. In 36 of the 39 patients the initial endocrine function of the pancreas was adequate. Three patients required exogenous insulin for varying periods of time after operation owing to graft endocrine insufficiency.

Exocrine pancreatic function was evaluated on the basis of the amount of amylase secreted in the urine per 24 h. The mean amylase secretion was considerably reduced during the first days after operation (2500 units per 24 h on days 1–3). Until the 14th day there was a steady increase in urinary amylase levels from 4500 to 25 000 units per day. One patient suffered complete exocrine graft failure. After recovering exocrine graft function, most patients developed metabolic acidosis which required adjustment with oral or intravenous sodium bicarbonate.

Kidney. In 34 patients there was sufficient renal function to obviate the need for haemodialysis. The mean serum creatinine level decreased to 2·3 (range 0·9–6·5) mg dl^{-1} on day 7 and to 1·8 (range 0·9–4·5) mg dl^{-1} on day 14.

Serum amylase and lipase

All patients had increased serum amylase and lipase levels. The mean peak levels were detected during the first 36 h following reperfusion of the pancreatic allografts. The amylase level was increased 3–15-fold and that for lipase 4–30-fold. Within the first week about two-thirds of patients had normal serum pancreatic enzyme levels.

Graft pancreatitis

Graft pancreatitis developed in 14 patients. In eight patients oedematous pancreatitis was diagnosed; the other six patients underwent reoperation between days 7 and 20, and peripancreatic and intrapancreatic necrosis was verified by microscopy. Extensive debridement of the graft and surrounding tissue was performed in all patients. In two patients resection of the pancreatic tail was necessary.

Long-term function

No patient died as a result of graft pancreatitis. All patients except one need no exogenous insulin. The 1-year graft function rate for the series of 39 patients was 87 per cent for both organs.

Morphological findings

Macroscopic appearance. During reperfusion and removal of the organs, and at the end of the period of cold ischaemia, no pathological changes were detected macroscopically. In 12 grafts a distinct, predominantly subcapsular, oedema became evident about 2 h after reperfusion, but there were no signs of parenchymal necrosis. During the final evaluation, superficial white areas aligned along the subcapsular blood vessels were found in 15 allografts. Confluent (five cases) and non-confluent (ten) areas could be differentiated. Macroscopic signs of parenchymal haemorrhage were not seen.

Light and electron microscopy. Sixteen pancreatic allografts were biopsied after perfusion with University of Wisconsin solution.

Morphology subsequent to perfusion

Immediately after perfusion, light and electron microscopy detected no changes in the exocrine parenchyma of the pancreas.

Morphology before reperfusion

Light microscopic examination at the end of the period of cold ischaemia showed an unevenly distributed, slight oedema of the lobular septa and the interacinar connective tissue. Most of the acinar epithelial cells contained the typical number of zymogen granules in the apical parts of the cell. In single acinar epithelial cells the cytoplasm was loosened by oedema. The nuclei of these cells were displaced to the periphery of the cytoplasm. The centroacinar cells showed no alterations. The vascular lumen was mainly free from erythrocytes.

Electron microscopy of the material showed that the swelling of the acinar epithelial cells was due to pronounced changes in the endoplasmic reticulum. An increasing distension of the cisternae of the endoplasmic reticulum had developed, initially giving the impression of dilatation and partial vacuolization. The remaining organelles were in part displaced to the periphery of the cells, and the nuclei were indented. Small amounts of fine flaky material and individual osmiophilic membranes were seen in the distended spaces of the endoplasmic reticulum.

Morphology following reperfusion

Erythrocytes were regularly demonstrable in the capillary lumen 30 and 90 min after reperfusion. Between the endothelial cells of the blood vessels polymorphonuclear leucocytes were found infiltrating the vascular walls and subsequently the perivascular connective tissue (*Figure 1*). In single acinar cells, reduced numbers and irregular distribution of the zymogen granules was evident. Fusion figures were seen between zymogen granules and vacuoles of lesser electron density (*Figure 2*).

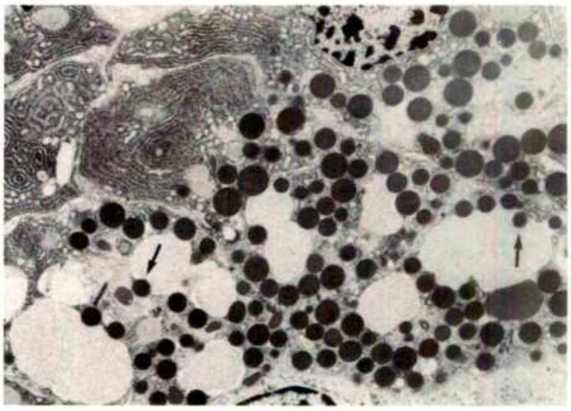

Figure 2 *Formation of vacuoles of different size within the acinar epithelial cells. Fusion (arrows) between zymogen granules and vacuoles of lesser electron density occurs 5 h after reperfusion. (Transmission electron microscopy, original magnification × 6700)*

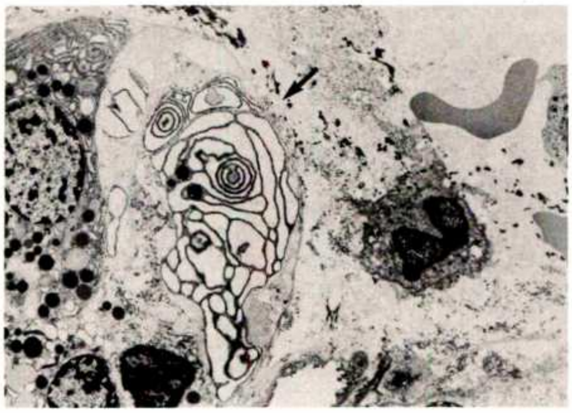

Figure 3 *Start of single cell necrosis (arrow) of acinar epithelial cells 6 h after reperfusion. There is destruction of cell membranes, involvement of capillaries, extravasation of erythrocytes, slight fibrin deposition and infiltration with granulocytes. (Transmission electron microscopy, original magnification × 4200)*

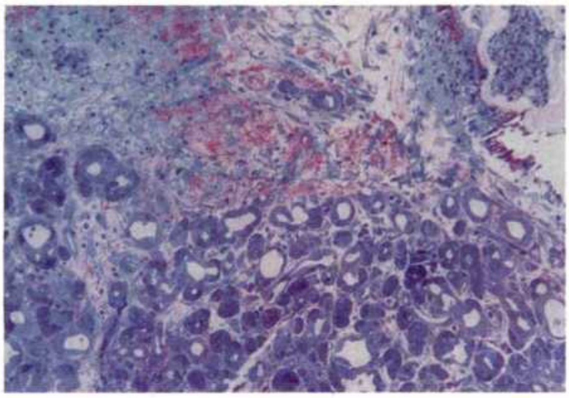

Figure 4 *Extensive necrosis of the exocrine pancreas with aggregation of macrophages at the edges. There is also distinct activation of local fibroblasts and neoformation of fibres. In areas of preserved parenchyma, exocrine activity is markedly reduced. (Basic fuchsine and methylene blue stain, original magnification × 260)*

Autophagolysosomes of varying size developed in the cytoplasm of the affected cells in ten cases. Their basic structure was in part characterized by membrane-like layered osmiophilic material and structures of different organelles. Granular particles were demonstrable with a homogeneous matrix similar to neutral lipids.

At 5–6 h after reperfusion, defects could be found in the plasma membrane of single acinar epithelial cells in six cases. Zymogen granules and part of the cytoplasm were liberated and entered the intercellular space. Haemorrhage, fibrin deposition and polymorphonuclear leucocyte infiltration of varying density occurred (*Figure 3*). The perivascular connective tissue was focally loosened by oedema and leucocyte infiltration.

In biopsies obtained during laparotomy, necrosis of the parenchyma and/or peripancreatic fatty tissue of varying intensity was demonstrated. In areas of intact exocrine pancreatic parenchyma the number of zymogen granules was markedly decreased, and in some cases patchy necrosis was seen with a marked increase in macrophage and fibroblast activity (*Figure 4*).

Discussion

The clinical results of pancreatic transplantation have improved since the introduction of the bladder drainage technique and new immunosuppressive strategies[13–15], and graft function rates after combined pancreatic–renal transplantation equal those after kidney transplantation alone[15–17].

Perioperative damage to the exocrine parenchyma is responsible for most of the early local and systemic complications of transplantation[7–9]. Considering the morphological findings and the typical blood and urine chemistry it is tempting to assume that ischaemia–reperfusion injury induces a form of acute graft pancreatitis. The morphological findings observed during reoperation in the present patients, and in previous biopsy and autopsy data, show inflammatory processes that correspond to the picture of autodigestive tryptic pancreatitis[18,19].

As in the acute pancreatitis induced by intravenous infusion of caerulein or choline-deficient and ethionine-supplemented diet, the initial stage of graft pancreatitis seems to be a disturbance of the 'secretory pathway'[19–25]. According to morphological criteria, normal enzyme synthesis, which probably depends on an intact energy metabolism, is altered. The strict compartmentalization necessary for acinar cell integrity (to prevent premature activation of proenzymes) is disturbed. Modifications of cellular integrity with imbalance of proteases and antiproteases caused by hypoxia can lead to activation of the lysosomal system, with crinophagy and acinar cellular necrosis[3,4,20–22,26].

The massive granulocyte infiltration found after reperfusion seems to be of special significance. Immunological factors do not play a major role, since such changes were not seen in isolated renal transplants[27]. Pancreas-specific leucotactic substances or oxygen free radicals could be responsible for this reaction. The pathophysiological consequences of this leucocyte infiltration are not fully understood but local and systemic reactions must be taken into consideration[28–30] as cascade-like activation of proenzymes via granulocyte hydrolases has been suggested[3,26].

The levels of pancreatic enzyme in serum and urine indicate that maximal damage and impairment of exocrine function develop during the first 3 days after transplantation. Following extreme parenchymal damage, complete failure of exocrine pancreatic function may coexist with normal endocrine function. Animal studies have shown similar disturbances of exocrine pancreatic function and regeneration of the acinar epithelium following induction of acute pancreatitis[31,32].

The aetiology of graft pancreatitis is different from that of 'ordinary' acute pancreatitis in humans. The deleterious effect of ischaemia and reperfusion might be of particular importance. In the very early postoperative phase studied here, immunological reactions are not involved. Known consequences of ischaemia include exhaustion of energy metabolism, tissue acidosis and the development of oxygen free radicals[33,34]. Changes in membrane structures such as the endoplasmic reticulum, demonstrated at the end of the period of cold ischaemia, may reflect exhaustion of energy metabolism. Similar changes have been described in the human pancreas following a severe reduction in blood flow, for example due to shock or local vasospasm[35–38]. The fact that pancreatitis can be induced by ischaemia and/or hypoxia, and that oedematous inflammation can proceed to the necrotizing form, has previously been shown only in animal models[39–42]. The present results demonstrate a possible role for hypoxia in the induction of ordinary acute pancreatitis in humans[43].

Irrespective of the different aetiological factors, there is still no conclusive knowledge about the initial morphological and biochemical processes that occur in acute pancreatitis[1,2,6,28]. Whether the same sequence of morphological events occurs in all forms of acute pancreatitis in humans remains uncertain. Further morphological and biochemical studies of pancreatic graft biopsies might allow identification of the initial reactions that develop in this disease.

A study in rats investigated the temporal relationship between acinar cell changes and alterations in the local microvasculature in oedematous pancreatitis produced by administration of caerulein 5 µg kg^{-1} h^{-1}. Samples were taken from experimental and control animals after 15 min, 30 min, 1 h and 2 h of caerulein infusion. Transmission electron microscopy showed ultrastructural acinar cell changes after 15 min whereas the earliest microvascular changes were seen after 30 min. Ultrastructural alterations in the acinar cells thus preceded local microvascular changes. Microvascular distortion appears to be a consequence and not a cause of pancreatitis in the caerulein model.

Caerulein-induced pancreatitis is associated with early changes in the acinar cell[1,2] and recent work has demonstrated marked distortion of the local microvasculature[3]. Studies using established models suggest that microvascular changes are critical in the pathogenesis of acute pancreatitis[3,4]. This study was undertaken to investigate the temporal relationship between acinar cell changes and alterations in the local microvasculature.

Materials and methods

Twelve male Sprague–Dawley rats weighing 350–450 g were anaesthetized with intraperitoneal chloral hydrate 36 mg per 100 g body-weight. Eight animals received an intravenous infusion of caerulein 5 µg kg^{-1} h^{-1} into the jugular vein, and four control rats received a similar volume of saline. Two experimental animals and one control rat were killed after 15 min, 30 min, 1 h and 2 h. Pancreatic samples were taken immediately after death, fixed in 2·5 per cent buffered glutaraldehyde solution, dehydrated in a graded alcohol series and embedded in Epon 812 (Agar Scientific, Stansted, UK). Ultrathin sections were cut with an LKB ultramicrotome (Leica, Cambridge, UK), stained with 2 per cent uranyl acetate followed by 1·3 per cent lead citrate, and viewed with a JEOL 200 EX electron microscope (Japanese Electron Optics Ltd, Tokyo, Japan). Multiple samples were taken from each pancreas and several sections processed from each sample.

Results

The ultrastructure of the pancreatic acini in the control rats was normal (*Figure 1*). In the experimental animals the first changes were seen after 15 min; these included vesiculation of the endoplasmic reticulum and the appearance of small cytoplasmic vacuoles (*Figure 2*). After 30 min vacuoles had increased in number. Zymogen granules of varying size and shape aggregated around the vacuoles (*Figure 3*). After 1 h of caerulein infusion the number of zymogen granules had decreased. After 2 h zymogen granules were sparse and large cytoplasmic vacuoles had developed that contained fragments of sequestered cytoplasm including zymogen granules, myelin-like figures and debris; the vacuoles in some instances were so large that they indented the cellular nuclei (*Figure 3*). Mitochondria appeared normal throughout the study period.

No abnormalities were seen in the microcirculation until 30 min after the start of caerulein infusion. The only change noted in the capillaries at this time was an increase in the number of fenestrae (*Figures 4* and *5*). After 1 h the number of micropinocytotic vesicles in the vessel walls had increased (*Figure 6*) and after 2 h there was gross irregularity of the endothelial lining of the vessel lumen (*Figure 7*). The basement membrane remained intact throughout the study. These vessels

also contained numerous red blood cells but showed no evidence of intravascular thrombosis. These findings were consistent in all sections studied and in all of the experimental animals.

Discussion

The pathogenesis of acute pancreatitis remains unclear. There is universal agreement on many of the major ultrastructural acinar cell changes that accompany acute pancreatitis, and the alterations described in the present study are characteristic of the model[4,5]. As pointed out by Adler and colleagues[5], no clear distinction has been made between factors that initiate acute pancreatitis and those that occur as a result of injury and subsequently play a role in further progression of the disease.

Possible involvement of the local microvasculature in the pathogenesis of acute pancreatitis was first recognized by Panum in 1862. Since then, numerous authors have confirmed the importance of vascular factors in pancreatitis[6,7] and in extrapancreatic organ impairment[8,9]. Workers using the *ex vivo* pancreatitis model[10] have demonstrated an early increase in capillary permeability. Recent experimental work using microvascular casting has confirmed that significant distortion of the local microvasculature occurs early in caerulein-induced pancreatitis[3], but the role of these changes in the pathogenesis of the disease remains unclear.

The vascular endothelium of visceral capillaries transports molecules by transcytosis. This occurs through vesicles, vacuoles and fenestrae[11]. The vascular features of an increased number of fenestrae, micropinocytotic vesicles and irregularity of the endothelial lining as seen in the present study are consistent with increased transport across the cell membrane[11]. This type of transport is specialized for water and solutes but whether the increased activity represents increased transport of fluid and other constituents from the periacinar spaces to the circulation is unclear.

Although the number of rats studied at each time interval is small (two experimental, one control), the present findings correspond closely with previous experimental work, which evaluated intra-acinar and microvascular changes in the same model separately[4,5]. The present observations demonstrate that acinar cell changes precede vascular changes. This is in contrast to previous work[10] and suggests that, in the caerulein model, vascular changes are not the critical initiating factor in the pathogenesis of disease.

Resection for adenocarcinoma of the body and tail of the pancreas

Adenocarcinoma of the pancreatic body and tail often presents late and is widely regarded as incurable by surgical resection; long-term survivors are rare. Thirteen patients underwent left resection (n = *7) or total pancreatectomy* (n = *6) in a consecutive series of 105 patients with carcinoma of the body or tail of the pancreas. Comparison was made with 17 patients with locally advanced or metastatic disease. Preoperative computed tomography predicted irresectable disease when a large perivascular lymph node mass was demonstrated. Preoperative angiography predicted irresectable disease when there was encasement or obliteration of the coeliac axis or its major branches, or of the superior mesenteric artery or vein. Splenic vessel involvement was sometimes compatible with resection. After resection, median survival was 13 (range 3–50) months, with a minimum follow-up of 2 years. Five patients survived more than 2 years, and three are still alive 30, 43 and 50 months after resection. Resection of carcinoma of the body or tail of the pancreas was possible in 12 per cent of patients and long-term survival was observed in some of these.*

Pancreatic adenocarcinoma has a poor prognosis. Most tumours arise in the head of the gland and patients present with obstructive jaundice. Patients with tumours of the body and tail often present late because of the vague non-specific symptoms and the absence of localizing features such as jaundice[1].

The purpose of this study was to review experience of adenocarcinoma of the body and tail of the pancreas. In recent years a more aggressive policy toward resection of these tumours has been pursued, with some encouraging results.

Patients and methods

A prospective record of all pancreatectomies for adenocarcinoma of the pancreas has been kept in the University Surgical Unit, Mannheim, since October 1972. In January 1992, all patients operated on before 1 January 1990 were reviewed. All those who underwent resection of adenocarcinoma of the pancreas arising to the left of the superior mesenteric vein were included. Patients with adenocarcinoma of the head of the pancreas who underwent Whipple's resection or total pancreatectomy were excluded. The operating records for 1988 and 1989 were inspected to identify patients with carcinoma of the body and tail of the pancreas who did not undergo resection. These years were chosen as they provided a sufficient number of adequately assessed patients for comparison with those undergoing resection.

Records of patients who underwent resection and those without liver metastases who did not were compared to try to identify features that might predict irresectability. Preoperative computed tomography (CT) and angiography were performed according to clinical indications and availability of the techniques. Radiologists' reports were scrutinized, with particular attention to features that might indicate resectability or irresectability. These features were compared with the surgeon's record of the operative findings.

All patients who underwent resection were followed prospectively. No patient was given adjuvant therapy after resection. Dates of recurrence of tumour and survival times were recorded. Patients who did not undergo resection were generally discharged from follow-up; information was sought from their family doctor about recurrence, further symptoms and length of survival.

Because of the small number of patients with resectable adenocarcinoma of the body and tail of the pancreas, life-table analysis was not used. The results are presented as brief clinical details, giving survival times for each patient.

Results

From 1 October 1972 to 31 January 1989, 709 patients with histologically verified adenocarcinoma of the pancreas were treated. In 604, the tumour was in the head of the gland. Of these, 142 patients (24 per cent) underwent pancreatoduodenectomy.

There were 105 patients with adenocarcinoma of the pancreatic body (63 patients) or tail (42); of these, 13 (12 per cent) underwent resection. In six cases this required total pancreatectomy, with resection of the portal vein in three. Seven patients underwent left-sided pancreatectomy (left hemipancreatectomy in six, subtotal resection in one). One of these patients required total gastrectomy for tumour invasion, one left nephrectomy for invasion of perinephric fat and two resection of tumour invading directly into the transverse mesocolon or by metastasis into the greater omentum.

For comparison, 17 patients were identified who were found at laparotomy to have irresectable adenocarcinoma of the body or tail of the pancreas. There were ten patients with locally advanced and histologically confirmed adenocarcinoma. Eight of these tumours definitely arose in the pancreas. In two cases the clinical impression was of a pancreatic tumour, but the histology was not diagnostic of the organ of origin. Seven further patients were found to have pancreatic adenocarcinoma of the body and tail with liver metastases.

The age and sex ratio of the different groups were similar (*Table 1*). In this retrospective survey it was not possible to determine any difference in the clinical features between patients suitable for resection and those with locally advanced disease. Pain in the upper abdomen and left upper quadrant was a common feature and weight loss was frequently seen. In

Table 1 *Age and sex distribution of patient groups*

	Median (range) age (years)	Sex ratio (M:F)
Total pancreatectomy (*n* = 6)	58 (43–65)	5:1
Left-sided pancreatectomy (*n* = 7)	68 (49–77)	4:3
Tumour irresectable because of local invasion (*n* = 10)	61 (55–78)	5:5
Liver metastases (*n* = 7)	64 (33–74)	2:5

Table 2 *Pathological diagnosis, tumour stage and survival in 13 patients who underwent resection of ductal adenocarcinoma of the body or tail of the pancreas*

Patient no.	Histological diagnosis	Stage*	Survival (months)
Distal resection			
1	Adenocarcinoma	$T_2 N_1$	>30†
2‡	Papillary ductal adenocarcinoma	$T_3 N_0$	8
3§	Schirrhous papillary ductal carcinoma	$T_3 N_1$	6
4	Ductal adenocarcinoma	$T_2 N_1$	26
5	Ductal adenocarcinoma	$T_2 N_1$	18
6	Ductal adenocarcinoma	$T_2 N_1$	7
7	Ductal adenocarcinoma	$T_2 N_0$	25
Total pancreatectomy			
8	Ductal adenocarcinoma	$T_3 N_1$	3
9	Ductal adenocarcinoma	$T_2 N_0$	>50†
10	Ductal adenocarcinoma	$T_2 N_0$	>43†
11	Ductal adenocarcinoma	$T_2 N_1$	13
12	Ductal adenocarcinoma	$T_3 N_1$	8
13	Ductal adenocarcinoma	$T_3 N_1$	11

*T_2, primary tumour 2–5 cm; T_3, tumour >5 cm; N_0, no involved lymph nodes; N_1, local peripancreatic nodes involved. †Patient still alive. ‡Patient underwent total gastrectomy and omentectomy; §patient underwent left nephrectomy and adrenalectomy in addition to left pancreatectomy

particular, there was no apparent difference in the duration of symptoms before diagnosis.

Four patients did not undergo endoscopic retrograde cholangiopancreatography. In the remainder, all but one showed abrupt occlusion of the pancreatic duct in the body or tail. Both CT and angiography were useful predictors of inoperability. On CT, the finding of a large mass extending beyond the pancreas with involvement of other organs usually, but not always, predicted irresectability. The presence of enlarged lymph nodes in the para-aortic, coeliac trunk and superior mesenteric areas also helped to predict irresectability. Angiography correctly predicted irresectability whenever there was occlusion or encasement of the superior mesenteric artery, common hepatic artery or coeliac trunk. Occlusion of the superior mesenteric vein on angiography was also a sign of irresectability. Encasement of the splenic artery and occlusion of the splenic vein were not absolute indicators of inability to perform resection. On two occasions, occlusion of the splenic vein was demonstrated in resectable tumours, although both of these lesions were large (>5 cm) with invasion into peripancreatic connective tissue. Resection of these tumours required subtotal pancreatectomy, with total gastrectomy in one case and left pancreatectomy plus excision of mesocolon in the other.

All patients who underwent resection had histologically confirmed pancreatic adenocarcinoma. Tumour type and stage are shown in *Table 2*.

Outcome

There were no postoperative deaths following resection. Two postoperative fistulas developed after left-sided pancreatic resection; one required multiple drainage procedures and the other closed but required a single drainage of a pancreatic fluid collection 3 months after operation. One patient is still alive with recurrence after left pancreatic resection. One patient required gastroenterostomy and another insertion of an endoprosthesis for obstructive jaundice. Patients with advanced (T_3) tumours generally had a poor prognosis, despite extensive resection of adjacent organs (*Table 2*).

After total pancreatectomy, two patients remain well with no evidence of tumour recurrence 43 and 50 months after surgery. Four patients have died from recurrence, 3–13 months after resection. Thus, in this highly selected group of six patients, two have survived more than 3 years.

Overall, the numbers surviving following resection of tumours of the body and tail were seven of 13 at 1 year, five at 2 years and two at 3 years.

Survival after laparotomy only

As expected, survival was uniformly short in patients with liver metastases: median 4 (range 2–9) months. All patients with irresectable locally invasive tumours died, at a median of 8 (range 2–15) months after operation. Only one patient survived more than 12 months.

Discussion

This study shows that, in a small selected group of patients with localized tumours of the body and tail of the pancreas, resection appears to be worthwhile, with relatively prolonged survival.

Two large series[2,3] of carcinoma of the body and tail of the pancreas reported resection rates below 8 per cent. The higher resection rate in the present series may represent improvement in diagnostic imaging with ultrasonography and CT, or perhaps may reflect a changing referral pattern. Nevertheless, the resection rate is still only half that for cancer of the pancreatic head in this unit[4], suggesting that there may be room for further improvement.

The low resection rate generally reported reflects the considerable pessimism felt about tumours of the body and tail of the pancreas. Very few survivors beyond 1 year have been recorded: Moossa[5] found only one in a 45-year literature review, and one of seven patients who underwent resection in a Japanese series[3] lived for 18 months. A recent review[1] concluded: 'the message is clear: ductal cancers distal to the head of the pancreas are virtually incurable'. Nevertheless, it seems reasonable to suppose that, if a patient presents with a resectable tumour, survival may be prolonged by a resection, even if ultimate cure cannot be achieved. This has been the authors' experience, with over half of patients who underwent resection surviving more than 1 year and 38 per cent surviving more than 2 years, despite the absence of very early (T_1) tumours. A recent report from the Mayo Clinic[6] supports the view that resection may be valuable, particularly in patients with tumours confined to the pancreas. Median survival in 26 patients who underwent resection of carcinoma of the body or tail of the pancreas was only 10 months, but two patients survived 5 years. A further case report[7] recorded a patient with poorly differentiated ductal adenocarcinoma who was alive and well 6 years after distal pancreatectomy.

A further argument in favour of resection is that it provides good palliation. Excision of a localized tumour will generally avoid the need for subsequent gastroenterostomy, as obstruction at the duodenojejunal flexure is uncommon after resection. In the present series, one of 13 patients has required subsequent gastroenterostomy. Three of ten patients with inoperable tumours required gastroenterostomy at the time of presentation.

A final decision about resectability in doubtful cases can be made only at operation. The value of preoperative investigation is in the identification of patients whose tumour will definitely be irresectable. A combination of CT and angiography can identify such patients. A large tumour mass extending outside the pancreas may be resectable if it does not involve major vascular structures outside the planned field of resection. Particular signs of irresectability are demonstration on CT of tumour involvement or lymph node enlargement around the coeliac trunk. Similarly, angiographic evidence of encasement of the coeliac trunk, common hepatic artery or left gastric artery, and of the superior mesenteric artery, also suggests irresectability. Occlusion of the superior mesenteric vein was also associated with an irresectable tumour, but three patients with involvement of the portal vein by tumour and otherwise localized disease were treated by resection of the tumour and portal vein in continuity, and interposition of a vascular graft. None of these patients survived beyond 12 months.

Evidence of involvement of the splenic artery and vein is not an absolute contraindication to resection. These vessels will be removed along with the pancreas, so that involvement with tumour is not in itself of importance. However, these radiographic signs were associated with large and invasive tumours at the limit of resectability. Both patients with splenic vessel occlusion sustained early local recurrence, with death at 6 and 8 months.

Tumour size also predicts local recurrence. The two patients with splenic vein thrombosis and early local recurrence both had tumours in excess of 5 cm in diameter. Four patients with a T_3 tumour died within 8 months of resection and the fifth after 11 months. However, the 6-year survivor noted by Billesbolle *et al.*[7] had a tumour measuring 11 × 10 × 7 cm, so such patients should not be denied resection if it is feasible.

The choice of operation for a tumour of the body or tail of the pancreas depends on its anatomical position. Tumours in the tail or at the junction of the body and tail are likely to be resectable with a conventional left-sided pancreatectomy, dividing the gland in front of the portal vein. Those of the body are more likely to encroach on the pancreatic neck and, if the patient is in a suitable general condition, total pancreatectomy is recommended for such lesions.

Aggressive surgical management of pancreatic adenocarcinoma can be justified only if there is a reasonable prospect of survival beyond 1 year and if operative mortality is minimal. If survival is generally less than 1 year, it is arguable that the patient has achieved little benefit from operation. If the operative mortality rate is high, any potential benefit of prolonged survival is cancelled out. In this unit, the operative mortality rate for resection of the pancreatic head is less than 3 per cent[8], with no deaths in over 150 consecutive pancreatoduodenectomies[4]. There were no postoperative deaths in the present 13 patients who underwent either total or left pancreatectomy.

The present results give a faint hope that resection may offer benefit to patients with localized adenocarcinoma of the body or tail of the pancreas. No firm conclusions can be drawn from the comparison with patients who did not undergo resection because, by definition, they had a more advanced stage of disease. Nevertheless, the observation that seven of this selected group of 13 patients survived beyond 1 year is encouraging. After total pancreatectomy, two patients survived more than 3 years.

Laparoscopic cholecystectomy in the Netherlands

Laparoscopic cholecystectomy was introduced into the Netherlands in the Spring of 1990. The aim of this study was to evaluate the results of the procedure in Dutch hospitals over the first 2 years to obtain some insight into its safety and efficacy in general surgical practice. A written questionnaire was sent to all 138 Dutch surgical institutions enquiring about conversion rate, complications (with emphasis on mortality rate and common bile duct injuries), operating time and hospital stay. The surgeons' opinions were also sought on possible contraindications such as previous operation, bile duct stones and cholecystitis, as were their estimations of the percentage of patients in their practice eligible for laparoscopic cholecystectomy. Data were obtained for 6076 laparoscopic cholecystectomies; the response rate was 100 per cent. Conversion to open cholecystectomy was necessary in 413 patients (6·8 per cent), mostly because of adhesions, cholecystitis, haemorrhage and unclear anatomy. Postoperative complications were reported in 260 patients (4·3 per cent). There were seven deaths (0·12 per cent) and 52 (0·86 per cent) bile duct injuries, of which 20 were recognized during laparoscopy. The mean operating time for the ten most recent patients in each institute was 70 (range 30–180) min and the mean hospital stay 4·5 (range 2–8) days. Previous lower abdominal operations were not considered to be a contraindication by 96 per cent of surgeons, whereas previous upper abdominal procedures were regarded as a contraindication by 66 per cent. After successful clearance of the bile duct at endoscopic retrograde cholangiopancreatography, only 12 per cent would perform an open procedure. Moderate cholecystitis was not considered a contraindication to laparoscopic cholecystectomy by 71 per cent of surgeons, but severe cholecystitis was a reason for open cholecystectomy for 83 per cent. In most surgical practices 70–80 per cent of patients were considered to be eligible for the laparoscopic procedure. In conclusion, laparoscopic cholecystectomy has gained rapid acceptance in the Netherlands. Although the number of bile duct injuries is high, the findings of this general survey are similar to those from highly specialized centres and match the overall results of conventional cholecystectomy.

In the Spring of 1990, laparoscopic cholecystectomy was introduced into the Netherlands, a country with 15 million inhabitants and an annual mean of 14 000 cholecystectomies[1]. The technique was adopted from Belgian, French and American colleagues. In the Autumn of 1990 several practical courses using an animal model were started, which accelerated the diffusion of the technique throughout the country. In addition to these courses, surgeons learned from colleagues or visited facilities with expertise in laparoscopic cholecystectomy. Certification was not issued, nor was it officially required.

Initial reports of a reduction in operative morbidity in laparoscopic compared with conventional cholecystectomy and patient demand provoked by the media stimulated rapid diffusion of the technique among Dutch surgeons. Most of the results reported in the literature are selected series from centres with extensive experience[2–4]. Limited data are available on the results of laparoscopic cholecystectomy in general surgical practice[5,6]. Results for the non-selected general patient population, previously treated by conventional cholecystectomy, should be collected to demonstrate the safety and efficacy of laparoscopic cholecystectomy for the general population. This study is a review of the results of laparoscopic cholecystectomy throughout the Netherlands over the 2-year period since its introduction.

Patients and methods

A written questionnaire requesting surgical data on laparoscopic cholecystectomy was sent to all 138 surgical institutions in the Netherlands. These institutions include eight university centres, 28 teaching hospitals and 102 community hospitals. The period covered by the survey extended from the first laparoscopic cholecystectomy performed in the Netherlands, in February 1990, to the start of the survey, in April 1992. Questions included the total number of laparoscopic cholecystectomies performed during that period, the number of conversions to the open procedure and the indications for this policy. Other questions related to postoperative complications, with the emphasis on common bile duct (CBD) injuries and deaths, as well as the mean operating time for the most recent ten procedures (or fewer if experience was limited) and the mean hospital stay including the day of admission and day of discharge.

The surgeons' opinions were sought on possible contraindications for laparoscopic cholecystectomy, particularly previous operations, CBD stones and cholecystitis. Finally, surgeons were asked to estimate the percentage of patients in their practice eligible for the laparoscopic procedure.

Results

A questionnaire compliance rate of 100 per cent was achieved. Completed forms were received from 103 institutions and data from the other 35 were collected by means of personal telephone calls to the surgeons.

In 134 of the 138 institutions 6076 laparoscopic cholecystectomies were performed during the period covered. A mean of 45 (range 1–230) procedures had been performed in each institution. Laparoscopic cholecystectomy was performed by one or two surgeons from the practising group in each hospital.

Conversion to an open procedure was necessary in 413 patients (6·8 per cent) (*Table 1*). The indications were mainly adhesions and cholecystitis. Haemorrhage, unclear anatomy, bile leakage from the gallbladder and certain technical problems were initially major reasons for laparotomy, but this changed as experience grew.

Postoperative complications were reported in 260 patients (4·3 per cent) (*Table 2*). Bile leakage was observed as leakage from the wound drain or as a fluid collection at postoperative ultrasonography, but this rarely resulted in laparotomy. The majority of haemorrhagic complications consisted of a fall in postoperative haemoglobin level that did not necessitate surgical intervention. CBD injuries were reported in 52 patients (0·86 per cent). Twenty of these were detected during the procedure and were corrected immediately; 32 lesions were found after surgery.

There were seven deaths (0·12 per cent). After repair of a laparoscopic CBD injury, three patients died from septicaemia, massive gastrointestinal haemorrhage and pulmonary embolus. Two patients died from myocardial infarction, one from incorrectly assessed bleeding from the cystic artery and one from rapidly spreading *Clostridium perfringens* septicaemia following a cystic duct leakage.

Table 1 *Indications for conversion to an open procedure during laparoscopic cholecystectomy*

Previous upper abdominal procedure	66	34
CBD stones *in situ*	89	11
CBD stones cleared after successful ERCP	12	88
Moderate cholecystitis	29	71
Severe cholecystitis	83	17

CBD, common bile duct; ERCP, endoscopic retrograde cholangiopancreatography

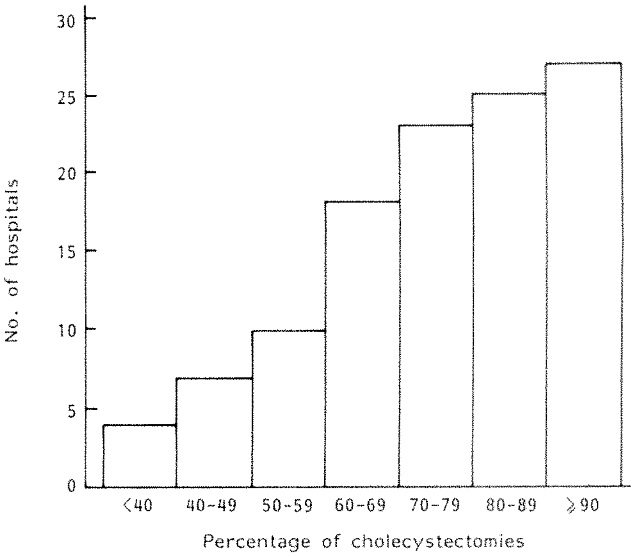

Figure 1 *Response of surgeons representing each group to the question: 'What percentage of cholecystectomies can be performed laparoscopically in your surgical practice?' About 15 per cent of surgeons had no opinion, mostly because of limited experience with the laparoscopic procedure*

The mean operating time was 70 (range 30–180) min. In centres with experience of fewer than 15 procedures, the mean operating time was 100 (range 55–200) min. This decreased to 66 (40–90) min after more than 15 procedures. The mean hospital stay was 4·5 (range 2–8) days.

Surgeons' opinions on contraindications for laparoscopic cholecystectomy are presented in *Table 3*, showing a range from absolute to relative contraindications. *Figure 1* shows the surgeons' rather divergent estimates of the percentage of patients who would be eligible for laparoscopic cholecystectomy.

Discussion

In this survey, 100 per cent compliance could be obtained because the Netherlands is a relatively small country with a coherent surgical group. After the introduction of laparoscopic cholecystectomy, surgeons from more than half of the hospitals were taught at the authors' centre, which obviously facilitates communication. Laparoscopic surgery is still in its early stages, with a mean experience of 45 cholecystectomies per hospital. The great interest in these procedures has contributed to accurate data registration. Limitations on the ability to request detailed information which is difficult to retrieve over a broad area were accepted to achieve high compliance and reliable data in this national survey.

Over 2 years after its introduction, almost all Dutch institutions now perform laparoscopic cholecystectomy; the exceptions are one cancer centre and three community hospitals. Most of the surgical teams started laparoscopic surgery during 1991. The experience of each hospital varies widely and is affected by the availability of laparoscopic equipment. More than one-third of hospitals performed procedures with instruments on loan from companies.

In view of the relatively limited experience, a conversion rate of 6·8 per cent is acceptable. In the early stages, surgeons show a low threshold for conversion to the open procedure. As experience grows, adhesions, cholecystitis, minor haemorrhage, technical problems and gallbladder perforations are less likely to lead to conversion.

The mortality rate was 0·12 per cent. In five of the seven patients, death was related to complications of laparoscopic cholecystectomy: in three to CBD injury, in one to cystic artery haemorrhage and in one to septicaemia following bile leakage. McSherry and Glenn[7] reported a 0·5 per cent mortality rate in non-complicated cholecystectomy caused mainly by cardiovascular disease. If laparoscopic cholecystectomy becomes routine, even lower surgical mortality rates can be expected than those reported in the present survey.

Complications of laparoscopic cholecystectomy can be related to laparoscopy, cholecystectomy or surgical procedures in general. Morbidity related to laparoscopy consists mainly of vascular or bowel injury due to insertion of the trocar and cannula and of pneumothorax as a result of the pneumoperitoneum, which occurred in nine (0·15 per cent) of 6076 patients. Despite the general use of cannulas with a safety shield for the first insertion, injuries do still occur. Insufficient pneumoperitoneum, usually during reinsertion of the trocar and cannula, reduces the distance between the abdominal wall and intra-abdominal structures, leading to injury. In cases of pneumothorax a relatively high intra-abdominal pressure (15 mmHg or higher) was used; this should be avoided.

Complications related to cholecystectomy consist of haemorrhage, CBD injury, bile leakage and retained stones. Severe haemorrhage during operation can be salvaged by conversion to laparotomy. One patient died because of an incorrectly evaluated cystic artery haemorrhage immediately after operation. This argues for overnight monitoring of the patient after laparoscopic cholecystectomy. Bile duct injuries are a major complication, detected in 20 patients during laparoscopy and 32 after surgery. The figure of 0·86 per cent CBD injuries found in the present study is higher than the 0·2–0·3 per cent reported for conventional cholecystectomy[8]. In the early stages, rates of approximately 1 per cent for CBD injury were reported by several authors[3,9,10]. The fact that the present study includes the early experience of all centres in one country might explain the relatively high incidence of bile duct injury. A decrease with time may be expected. Three patients died from complications of the CBD injury; these injuries were all detected after operation. If an injury is suspected during laparoscopy, operative cholangiography can demonstrate it and immediate treatment is then mandatory. Bile leakage was usually managed without a second procedure and can be detected after operation by the combination of abdominal pain in the right upper quadrant and a subhepatic fluid collection shown by ultrasonography or leakage demonstrated by cholescintigraphy.

The low number of retained stones reported in the survey may reflect the preoperative selection criteria, which included the absence of signs of CBD stones. Furthermore, the follow-up has been short and the incidence might be underestimated. Operative cholangiography is not routine during laparoscopic cholecystectomy in the Netherlands.

Morbidity related to surgical procedures in general consisted of wound infection, and pulmonary, cardiac and thromboembolic complications. The infection rate of 1·65 per cent is lower than that in conventional cholecystectomy. Although two patients died from myocardial infarction, the number of general complications was low. Incisional hernia occurred in five patients at the umbilical site and in two at the epigastric cannula insertion site. Since the gallbladder is usually extracted through the umbilical incision, which is sometimes enlarged, separate fascial closure is recommended.

The mean operating time decreased from 100 min for the first 15 procedures to approximately 1 h, which indicates a 'learning curve'. The mean hospital stay, including the day of admission and that of discharge, was 4·5 days, which implies that there has been a reduction in the hospital stay for complicated and uncomplicated cholecystectomy in the Netherlands: the mean stay was 13·5 days before the introduction of laparoscopic cholecystectomy.

At the introduction of laparoscopic cholecystectomy, a previous laparotomy, CBD stones and cholecystitis were assumed to constitute relative contraindications. The present Dutch surgeon's opinion is more liberal. Previous lower abdominal incision is hardly felt to be a contraindication, but there is some reserve with regard to upper abdominal operations. With the back-up of an experienced gastroenterologist to perform endoscopic retrograde cholangiopancreatography, CBD stones are generally not felt to be a major contraindication for laparoscopic cholecystectomy. Still, most surgeons prefer prior clearance of the bile duct before attempting the operation. The eligibility of patients for a laparoscopic approach to cholecystitis depended on the surgeon's experience. Surgeons estimated that 70–90 per cent of patients with gallstone disease would benefit from laparoscopic cholecystectomy.

In conclusion, laparoscopic cholecystectomy is rapidly being implemented in the Netherlands. Although no accreditation system exists, the procedure is relatively safe in general surgical practice. The number of conversions and serious complications such as bowel injury by the trocar and cannula and CBD injury are expected to decrease as most of the surgical institutions have passed the lag phase of the 'learning curve'. The anticipated reductions in surgical morbidity rate and hospital stay will benefit 70–90 per cent of patients with gallstone disease in the Netherlands over the next few years.

Pancreatoduodenectomy with stapling devices

R. Rieger and W. Wayand

Second Surgical Department, Allgemein öffentliches Krankenhaus der Stadt Linz and Ludwig Boltzmann Institut für operative Laparoskopie, Linz, Austria

Correspondence to: Dr R. Rieger, Zweite Chirurgische Abteilung, Allgemein öffentliches Krankenhaus, Krankenhausstraße 9, 4020 Linz, Austria

Surgical stapling instruments have found wide application, particularly in gastrointestinal procedures[1,2]. Their use in pancreatic surgery has not been great, although encouraging clinical results[3,4] in distal pancreatectomy were published more than 10 years ago. In a consecutive series of 26 Whipple procedures, the usefulness of TA55 and GIA50 staplers (US Surgical, Norwalk, Connecticut, USA) for transection and anastomosis of the pancreas has been evaluated. The indications for surgery were pancreatic cancer (13 patients), ampullary carcinoma (six), cancer of the common bile duct (one) and chronic pancreatitis (six).

Surgical technique

The pancreas was prepared by blunt dissection between the gland and portal vein so that the surgeon's finger could pass easily between them. The TA55 stapler was loaded with a 3·5- or 4·8-mm cartridge, depending on the thickness of the pancreas. The opened jaws were passed around the pancreas and a double line of stainless steel staples placed across the gland. The pancreas was then divided with a knife, using the cartridge as a cutting guide.

The jejunum was divided 5 cm distal to the duodenal flexure with the GIA50 stapler. Pancreatojejunostomy was performed by approximating the stapled jejunum to the stapled pancreas. A single layer of interrupted atraumatic sutures was placed between the pancreatic capsule and the jejunum, 5 mm posterior to the staple line. By knotting the stitches, the pancreas was attached to the jejunum to complete the posterior aspect of the anastomosis. Next, two staples at the site of the pancreatic duct and the corresponding site of the jejunum were removed to provide drainage of pancreatic juice into the jejunum. The anastomosis was completed by an anterior layer of sutures, as described for the posterior layer.

Results

The technique was applicable in 24 of the 26 patients. In one patient with chronic pancreatitis and another with locally advanced pancreatic cancer it was not possible to encompass the pancreas with the TA55 stapler.

In no instance did stapling the pancreas damage the parenchyma. Minor bleeding from the staple line was observed in 13 patients but stopped spontaneously in the majority of cases. One 72-year-old patient died from cardiac failure on day 4 after operation; the pancreatic bed was unremarkable at autopsy. There were five complications: re-exploration for haemorrhage (one) and wound infection (four). No pancreatic fistula arose and no patient developed exocrine or endocrine pancreatic insufficiency within a follow-up of 20 months.

This technique provides a simple, safe and quick way of transecting the pancreatic parenchyma. The uniform closure of the pancreas and jejunum provides excellent preparation for the pancreatojejunostomy, and may contribute to a reduced morbidity rate.

New technique of open laparoscopy

A. Ahmad and A. R. Quayle

Department of Surgery, Macclesfield District General Hospital, Victoria Road, Macclesfield SK10 3BL, UK
Correspondence to: Mr A. R. Quayle

Laparoscopic cholecystectomy has become a routine procedure. Introduction of a Veress needle to establish pneumoperitoneum and subsequent blind insertion of the subumbilical trocar with cannula carry a definite risk that is clearly higher in patients who have undergone previous surgical operations. Safety guards incorporated into trocars reduce the risk but, as will be appreciated during laparoscopic visualization of trocar insertion, the protective sleeve may be held back by the peritoneum until the trocar has advanced well into the abdominal cavity. Gut and vascular injury are not uncommon[1].

Open laparoscopy using a Hasson cannula was developed to obviate the need for blind puncture with a Veress needle and subsequent blind insertion of the subumbilical trocar. A technique of open laparoscopy well suited to laparoscopic surgery is described.

Surgical technique

A Veress needle is not used. A 2-cm skin incision is made as usual in the subumbilical position. The linea alba, which is picked up using a pair of tissue-holding forceps, is divided with scissors. The peritoneum is held with a pair of haemostats, and a 1-cm opening is made with scissors. A finger is pushed through the opening and swept around the posterior aspect of the anterior abdominal wall to confirm that it is free of adherent intra-abdominal contents. A purse-string suture is placed around the opening using Ethibond (Ethicon, Edinburgh, UK) on a J shaped needle. A 10-mm cannula is inserted into the opening without a trocar. A single knot is tied on the purse-string suture so that it holds the cannula tightly (*Figure 1*). A rubber tube of about 5 cm length is created by division of the middle portion of a simple red-rubber Jaques' catheter. The ends of the purse-string suture are passed through it and the rubber tube is 'snugged down' with a haemostat on to the cannula, holding it tightly (*Figure 2*). This manoeuvre forms an adequate seal to withstand pneumoperitoneum of 12 mmHg pressure. During extraction of the gallbladder the rubber tube is removed and the purse-string suture loosens. It is then a simple matter to tighten the purse string and obtain an adequate closure of the opening in the linea alba.

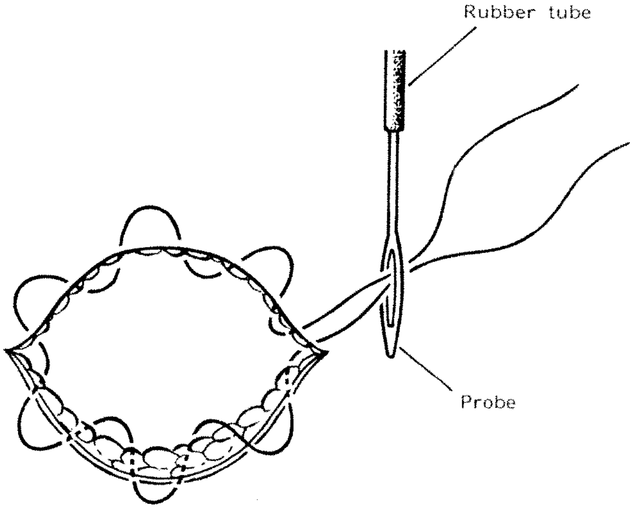

Figure 1 *The carefully placed purse-string suture*

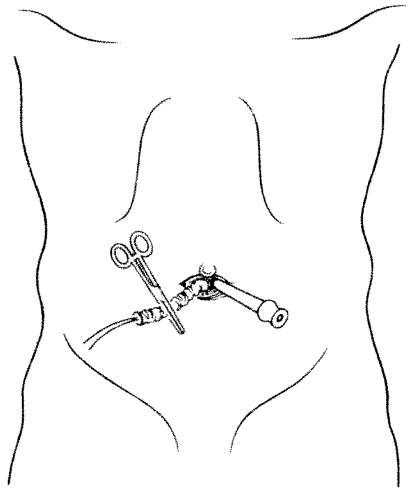

Figure 2 *The rubber tube snugged down on the 10-mm port (size of subumbilical wound enlarged for clarity)*

Discussion

Use of an endotracheal tube with insufflation of its balloon for prevention of gas leak[2] and of a grooved director for easy extraction of the gallbladder[3] have recently been reported. The method described obviates the need for the use of these methods. Advantages of the technique include: (1) less chance of injury to intra-abdominal structures, especially in patients with previous operations; (2) easy extraction of the gallbladder with stones by release of the purse string; and (3) easy and secure closure of the linea alba after extraction of the gallbladder.

The technique does not involve a larger skin incision, and there is no gas leak from the wound if the purse-string suture is placed accurately.

Percutaneously placed Wallstent endoprosthesis in patients with malignant distal biliary obstruction

J. Stoker, J. S. Laméris and J. Jeekel*

*Departments of Radiology and *Surgery, University Hospital Dijkzigt, Dr Molewaterplein 40, 3015-GD Rotterdam, The Netherlands*

Correspondence to:
Dr J. Stoker

Seventy-five patients with malignant distal biliary obstruction were treated by percutaneously placed self-expandable Wallstent endoprostheses for palliative drainage. The stent diameter was 1 cm and its length 3·5–10·5 cm. Early complications occurred in 16 patients (21 per cent); they were related to the endoprosthesis in five (7 per cent) and serious in six (8 per cent). The 30-day mortality rate was 15 per cent, with a 1 per cent procedure-related mortality rate. Sixty-five patients died 6–365 (median 87) days after stent insertion and four had recurrence of obstruction after 21–341 (median 152) days. Reobstruction was the result of tumour ingrowth in one patient, angling of the stent in one and an unestablished cause in two. Ten patients were alive without obstruction 31–383 (median 65) days after stent insertion. Percutaneous use of the Wallstent endoprosthesis allows easy insertion; reobstruction is rare.

Inoperable malignant non-hilar biliary obstruction may be palliated by endoscopic or percutaneous insertion of an endoprosthesis. Currently available plastic prostheses frequently block with sludge and, less commonly, migrate. Changes in stent design to reduce blockage rates have met with only limited success[1].

Self-expandable metallic endoprostheses have recently been introduced[2]. These have a large inner diameter after release; this is an important factor in prolonging stent patency[3]. The expansile force of the stent against the bile duct wall prevents migration. The Wallstent endoprosthesis (Wallstent; Schneider, Bülach, Switzerland) used in the present study is composed of a stainless steel braided self-expandable mesh and is loaded in compressed form on a small (7 Fr) delivery catheter, to be released by progressive withdrawal of the enclosing membrane. Experience with the Wallstent endoprosthesis and its role in the stenting of malignant distal biliary stricture are described.

Patients and methods

Between 1989 and 1991, 75 patients with inoperable malignant biliary obstruction distal to the liver hilum were treated by percutaneous insertion of a Wallstent endoprosthesis. There were 36 men and 39 women with a median age of 72 (range 36–91) years. Fifty-three patients had pancreatic carcinoma, four cholangiocarcinoma, 12 periportal metastasis and six obstruction due to miscellaneous malignant causes. Histological or cytological confirmation of the diagnosis was obtained in 47 patients (63 per cent). In the remaining 28 patients the diagnosis was based on clinical and radiological findings, and follow-up gave no doubt concerning the diagnosis. The majority of patients had treatment before percutaneous stenting (*Table 1*). Eighteen patients had cholangitis before the percutaneous procedure. The serum bilirubin concentration was measured before stent placement in 67 patients and the median value was 185 (range 29–566) μmol/l (normal range 4–14 μmol/l).

All percutaneous transhepatic biliary drainage procedures were performed under ultrasonographic and fluoroscopic guidance. Broad-spectrum antibiotics were used during the 12 h before and after each procedure. All stents had a diameter of 1 cm; the length varied from 3·5 to 10·5 cm. Balloon dilatation was performed before stent insertion in the first five patients. This was subsequently abandoned as the prostheses continued to expand for a few days after placement. Plain abdominal radiography confirmed the position and degree of expansion of the stents 1–14 days after insertion.

The effect on jaundice, complications and follow-up were recorded for all patients. Early complications were those occurring within 30 days of stent placement. Cholangitis was defined as fever >38°C in the absence of other explanations. Bleeding was assumed after a reduction in the haemoglobin level $\geq 0{\cdot}5$ mmol Fe^{2+} per litre in the absence of other explanations. The serum bilirubin concentration was recorded approximately 1 month after stent placement. The patency period of the prosthesis was taken as the interval between its insertion and the occurrence of biliary obstruction, as defined by clinical symptoms, and ultrasonographic and cholangiographic findings.

Table 1 *Previous therapy in 75 patients treated by percutaneous Wallstent endoprosthesis insertion*

Failed endoscopic attempt	50
Failed endoscopic replacement	12
Previous percutaneous endoprosthesis	1
Palliative biliary bypass	5
Whipple's procedure	1
Cholecystectomy	1
Gastroenterostomy	5
External radiotherapy	5

Results

Endoprosthesis insertion (*Figure 1*) was successful and uneventful in all patients. Stent expansion to >80 per cent of the maximal diameter was seen in all cases. Pre-existing cholangitis resolved in all but two patients. Serum bilirubin concentration after stent insertion was measured in 47 patients, and showed a decrease in all, with a level of less than twice the upper limit of normal in 21 patients after 30 days.

Early complications occurred in 16 patients (21 per cent); they were related to the stent in five (7 per cent) and serious in six (8 per cent) (septicaemia, four; pleural empyema, one; reobstruction, one). Seven patients had cholangitis, including two with pre-existing cholangitis. Four of these seven had septicaemia but all recovered following antibiotic administration. In four patients bleeding of the transhepatic tract was noticed during catheter manipulation, and controlled by leaving the drainage catheter in place for 2 weeks after stent insertion. Bleeding, bile leakage along the catheter and catheter dislocation occurred in one patient each and were treated conservatively. A debilitated patient with a transpleural catheter developed pleural empyema; no therapy was performed as the patient was terminally ill. Reobstruction due to angling of the stent occurred in one patient 21 days after insertion.

0007-1323/93/091185-03 © 1993 Butterworth-Heinemann Ltd

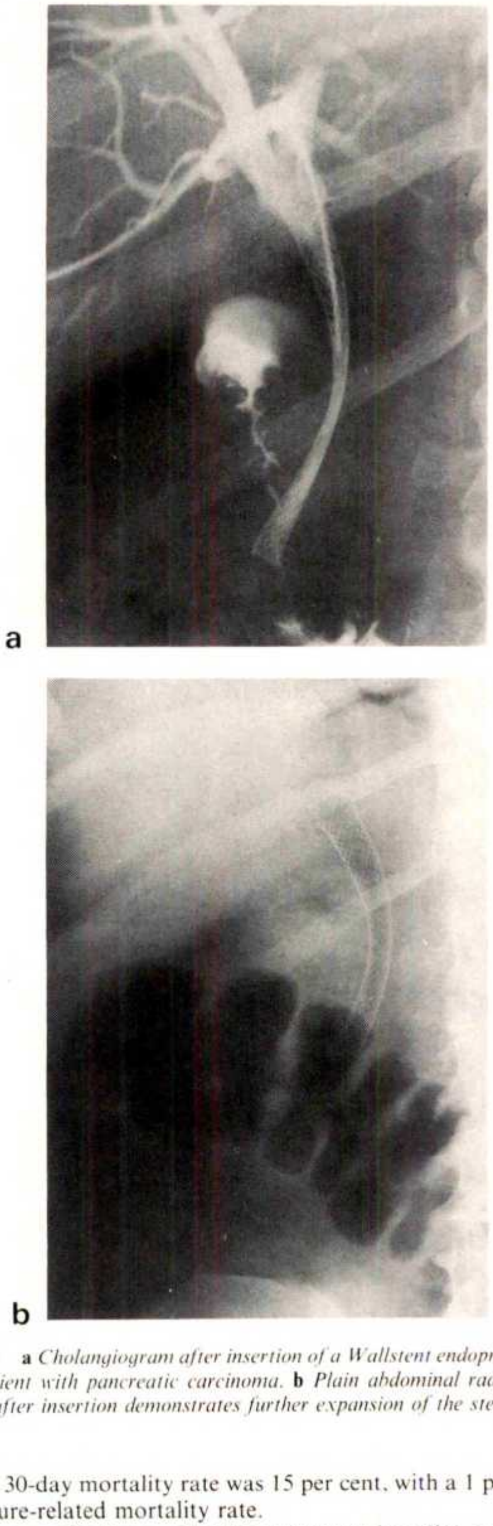

Figure 1 **a** *Cholangiogram after insertion of a Wallstent endoprosthesis in a patient with pancreatic carcinoma.* **b** *Plain abdominal radiograph 4 days after insertion demonstrates further expansion of the stent*

The 30-day mortality rate was 15 per cent, with a 1 per cent procedure-related mortality rate.

Late complications, other than recurrent jaundice, occurred in two patients. One patient developed a pressure ulcer of the duodenum opposite the stent and another had melaena at 45 days that was attributed to the prosthesis because no other cause could be found. Gastroenterostomy was necessary in two patients.

Recurrent jaundice due to stent obstruction occurred in four patients after 21, 127, 176 and 341 days. Tumour ingrowth caused reobstruction in one patient and angulation of the stent caused recurrent jaundice in another. The first patient was treated by catheter drainage, the second by proximal lengthening of the stent. There was clinical suspicion of reobstruction in two terminally ill patients, but no definitive cause was established.

Ten patients remain alive after a median follow-up of 65 (range 31–383) days, with no recurrence of obstruction so far. The other 65 patients died, with a median survival of 87 (range 6–365) days after stent placement. The four patients with reobstruction were in this group.

Discussion

Curative surgery is often not feasible in patients with malignant distal biliary obstruction. Palliative biliary bypass may be performed but non-surgical drainage by stent insertion has proved an important alternative and provides better results than biliary surgery in many institutions[4–7]. Efforts have been made to design an endoprosthesis that is easy to insert and remains patent until death. The major disadvantage of the plastic stents currently available is reobstruction by sludge. Increase of stent diameter might prolong patency but is limited by several factors, such as more difficult manipulation and the possibility of more complications. The design of the self-expandable Wallstent endoprosthesis, with its small delivery catheter, large inner diameter, relatively small surface area and fixation against the wall, seems advantageous in theory, but trial results are required.

Before comparing the present study with others (especially endoscopic) on biliary stenting, differences in study populations should be considered. The majority of patients in the present study had one or more failed endoscopic attempts. This increases the risk of early complications, especially cholangitis, and this patient group is probably more difficult to treat, as one method has already failed.

Early complications in the present series, predominantly cholangitis, occurred in 21 per cent of patients, a rate comparable to that seen with plastic stents[7–11]. The majority of the early complications were caused by the initial catheter drainage and most of these patients had a previous failed endoscopic attempt, thus increasing the risk of cholangitis. Most complications were minor and other studies of the Wallstent endoprosthesis have reported a wide range of early complications[2,12–14].

Reobstruction of plastic stents in malignant distal stricture occurs in approximately 20–40 per cent of cases after 3–5 months[4,5,7,10,11,15] and therefore the rate (5 per cent) associated with the Wallstent endoprosthesis in the present series compares favourably. Blockage by sludge, the major problem in biliary stenting, has become a rare cause of reobstruction[2,12–14,16–19]. Tumour overgrowth seldom causes reobstruction when stents of an adequate length are used. Tumour ingrowth through the mesh of the stent occurs but, since the inner stent diameter is large and survival short, stent obstruction will remain a relatively rare event.

Besides its expanding force the Wallstent prosthesis has a straightening force; this may result in the stent not retaining the form of the bile duct, with subsequent occlusion of the proximal end of the device by the bile duct wall, as occurred in one patient in the present study. This problem can be treated by proximal lengthening of the stent and prevented by using longer stents initially. Reintervention is more easily performed than with plastic prostheses, because another stent or catheter can be placed through the lumen, without the need for stent removal.

The use of the Wallstent endoprosthesis increases the cost of the procedure, and this must be weighed against the reduction in the rate of reobstruction and consequent decrease in the costs of reintervention and rehospitalization[20].

Percutaneous insertion of the Wallstent endoprosthesis to establish definitive biliary drainage without recurrence of jaundice by reobstruction was accomplished in most patients in this study.

Palliation of biliary obstruction in patients with advanced breast cancer using endoscopic stents

P. L. R. Mitchell, V. J. Harvey, M. R. Lane*, B. D. Evans, P. I. Thompson and I. Hamilton*

*Departments of Medical Oncology and *Gastroenterology, Auckland Hospital, Auckland, New Zealand*

Correspondence to:
Dr P. L. R. Mitchell, Department of Medicine, The Royal Marsden Hospital, Downs Road, Sutton, Surrey SM2 5PT, UK

Endoscopic insertion of a biliary endoprosthesis was successful in eight patients with extrahepatic biliary obstruction caused by breast cancer metastases. The serum bilirubin level was significantly reduced in seven patients and in four this was accompanied by marked symptomatic improvement. Endoprostheses required replacement after a median of 8 (range 3–127) weeks. Two patients responding to systemic anticancer therapy survived 27 and 43 months. Endoscopically placed stents offer effective palliation of extrahepatic biliary obstruction caused by metastatic breast cancer and long-term survival may be possible.

Malignant obstruction of the extrahepatic bile ducts may result from metastatic cancer to the area of the pancreatic head and porta hepatis. This produces distressing symptoms of jaundice, pruritis, nausea and anorexia.

Palliation of extrahepatic biliary obstruction can be achieved surgically, but recent attention has focused on non-operative methods. The development of endoscopic insertion of endoprostheses allows palliation with a short hospital stay and low morbidity and mortality rates[1,2]. In a series of 221 patients with pancreatic cancer, endoscopic management was successful in 90 per cent and there was a procedure-related mortality rate of only 2 per cent[3]. Similar results have been obtained in this institution[4]. Application of the technique to eight patients with breast cancer is described.

Patients and methods

Of 140 patients referred for endoscopic management of malignant extrahepatic biliary obstruction between June 1987 and November 1990, eight women presented with metastatic breast cancer obstructing the distal common hepatic duct or common bile duct (CBD). The median age was 50 (range 40–63) years and all patients were jaundiced at presentation with a serum bilirubin level $\geqslant 90$ mmol/l. All had multiple sites of tumour spread at the time of the initial procedure, including liver metastases in five patients. Extrahepatic biliary obstruction was demonstrated by ultrasonography in each patient.

Two patients had previously been treated for biliary obstruction. In one, cholecystoenterostomy had produced no improvement; percutaneous biliary drainage and chemotherapy had been given with no significant benefit. At endoscopic retrograde cholangiopancreatography (ERCP) the stricture was seen to be proximal to the surgical bypass. The second patient had achieved complete remission of a metastasis to the pancreatic head following chemotherapy 10 months previously and presented this time with further obstruction.

Insertion of an endoprosthesis was attempted at the time of diagnostic ERCP using a standard technique[3]. A small sphincterotomy was made to facilitate access to the CBD. Most initial procedures were performed using an Olympus JF1T10 side-viewing duodenoscope (Keymed, Southend-on-Sea, UK) with a 2·8-mm diameter instrument channel, allowing the insertion of a 7-Fr prosthesis. Replacement of prostheses was usually undertaken with an Olympus TJF10 endoscope with a 4·2-mm channel allowing passage of a 12-Fr stent. Straight prostheses with side flaps to prevent migration were used.

Results

Prostheses were successfully placed at the time of initial endoscopy in seven patients and by a combined endoscopic and percutaneous approach in one. Two patients suffered complications: minor haemorrhage that did not require transfusion and transient antibiotic-related renal failure.

One patient died 5 days after the procedure from pulmonary embolism. The other seven achieved successful drainage, defined as a 50 per cent fall in serum bilirubin level or relief of jaundice within 30 days. Six patients required stent replacement after a median of 8 (range 3–127) weeks (*Table 1*). Occlusion of the endoprosthesis was usually heralded by jaundice and cholangitis.

Six patients improved symptomatically; four of these showed marked improvement and returned to full activity. Seven patients died at 5 days, 5, 11, 19, 31 and 31 weeks, and 43 months after the initial procedure. One patient remained alive at 27 months. The two longest survivors showed prolonged responses to hormone treatment. Neither had initial liver metastases. One patient remained stable on megestrol acetate for 18 months and the other died at 43 months after responding to tamoxifen and megestrol acetate therapy.

Discussion

Malignant extrahepatic biliary obstruction carries a poor prognosis especially if caused by pancreatic cancer, where the median survival after palliative treatment[1,5] is approximately 4 months. In patients with metastatic extrahepatic biliary obstruction in the presence of widely disseminated disease the outlook is also poor; in one study[6] eight of 12 patients died within 2 months.

In a series of seven patients with breast cancer treated by various non-endoscopic means[7], a similar success rate for relief of obstruction and comparable survival rate to those in the present study were observed, but only three patients had other sites of metastatic disease. It was concluded that hepatic metastases precluded significant palliation. In the present study all eight patients had breast cancer metastases at multiple sites; despite this, only two failed to improve symptomatically and six survived longer than 2 months.

The major complication of the procedure was occlusion of the endoprosthesis. Replacement was required after a median of 8 weeks and was often undertaken as an outpatient procedure.

Extrahepatic biliary obstruction caused by metastatic breast cancer can be effectively palliated by endoscopic insertion of a stent despite the presence of widespread metastases. Prolonged survival may be seen in patients responding to systemic anticancer treatment.

Role of early and extensive surgery in the treatment of severe necrotizing soft tissue infection

D. Voros, C. Pissiotis, D. Georgantas, S. Katsaragakis, S. Antoniou and J. Papadimitriou

Second Department of Surgery, School of Health Sciences, University of Athens, Athens, Greece

Correspondence to:
Dr D. Voros, 18 Kifissias Avenue, 115 26 Athens, Greece

Forty-two patients with necrotizing soft tissue infection are reviewed. Bacterial culture revealed between two and seven types of micro-organism in each patient. All patients were treated with radical surgical debridement and a combination of antibiotics. In 30 patients, early diagnosis and treatment resulted in only two deaths. Delayed surgical intervention in 12 patients transferred from outside hospitals was followed by nine deaths. Predisposing factors and site of infection did not affect outcome. Of 26 patients with systemic manifestations of sepsis, 16 survivors responded well to initial surgical debridement.

The mortality rate of patients with necrotizing soft tissue infection is high: 30–60 per cent[1–5]. The terminology used for these infections is related to the kind of pathogen, the tissues involved and the presence or absence of gas in the tissues, e.g. necrotizing fasciitis, streptococcal gangrene, synergistic gangrene, and clostridial or non-clostridial myonecrosis. Necrotizing soft tissue infection is usually a superimposed process in patients with impaired humoral and cellular immunity resulting from previous inflammatory conditions or other factors such as diabetes or alcoholism.

This report describes the details of 42 patients with soft tissue necrotizing infection treated over a 12-year period.

Patients and methods

The 42 patients comprised 28 men and 14 women with a mean age of 55·2 years. Causative mechanisms and predisposing factors were identified on admission, with an evaluation of the extent and severity of tissue involvement. Resuscitation was accomplished within 4–6 h. Fluid from involved tissues was collected for bacteriological analysis and a combination of antibiotics administered.

Under general anaesthesia, extensive radical debridement and resection of all involved tissues was performed. The size of potential defects or cosmetic considerations were not immediate concerns.

Results

The most frequent locations of infection were the abdominal wall (11 patients), the lower extremities (ten) and the perineum (six); both the perineum and hypogastrium were involved in six patients (*Table 1*). Of the six patients with necrosis of the perineum alone, four had Fournier's gangrene; four patients required a diverting colostomy. In three of these patients extension into retroperitoneal tissues was found during surgery. The type of infection varied as shown in *Table 1*. Necrotizing fasciitis was the most frequent manifestation (15 patients). The infections were all polymicrobial, yielding from two to seven (mean 3·5) types of micro-organism per patient. Ten patients had mixed aerobic and anaerobic flora.

The nature of the necrosis and type of surgery in patients with postoperative infection are shown in *Table 2*; all 11 patients had only local signs. A pre-existing neglected purulent process was present in 17 patients, including seven with an intra-abdominal infection, eight with a perineal abscess and two with neglected ischaemic necrosis of the lower limb. In 12 patients predisposing factors such as diabetes (five), immunosuppression (two), alcoholism (two) and multiple trauma (three) were present. Despite the contribution to the

development of necrosis, these conditions did not adversely affect outcome and none of these patients died.

Organ failure occurred in 18 patients and was present on admission or developed as a result of sepsis (*Table 3*). The patients required between two and seven (mean 3·5) surgical debridements during hospitalization, excluding procedures required for reconstruction.

There were 11 deaths. Of 12 patients in whom surgical debridement was delayed because of transfer from an outside hospital, nine died. Of 30 patients who underwent radical surgery within the first 24 h, there were only two deaths. Two patients with necrosis of the retroperitoneal tissues survived. Sixteen patients had only local signs of infection and 26 had systemic manifestations of sepsis. In the group with local signs, only one patient died; in the other group, the ten patients who died continued to have systemic manifestations of sepsis after initial surgery. Patients who responded favourably to the initial debridement did well.

Discussion

Severe necrotizing soft tissue infections are known to be polymicrobial. The most severe cases are those in which mixed aerobic and anaerobic flora are found[6]. Necrotizing infections of the trunk (mainly the lower abdomen and perineum) are frequently the result of a neglected postoperative complication or of trauma[3,4]. If the extremities are involved, it is usually the result of trauma or needle puncture and extravasation of drugs.

Predisposing factors include diabetes, alcoholism and immunosuppression (malignancy or chemotherapy). Early treatment in these patients had a favourable outcome. A pre-existing neglected focus could be considered as another predisposing factor. In 17 patients, neglected perineal abscesses and intra-abdominal infections existed before the necrotizing infection, and in four of these patients the infections arose from badly or inadequately treated postoperative complications.

The patients in this series can be divided retrospectively into two groups according to the time of treatment. In previous studies the authors stated that prompt and aggressive debridement remains the cornerstone of management[5]. Radical surgical debridement and antibiotics are of no value if the necrotic process has already extended[7,8]. In 12 patients in whom surgery was delayed there were nine deaths. In previous reports[1–5], the mortality rate ranged from 30 to 60 per cent. The difference in mortality rates does not represent the severity of these infections but rather the difference and timing of the methods of treatment.

Woodburn *et al.*[9] reported five fatal cases of retroperitoneal necrotizing fasciitis. In the present series, there were three patients with sepsis of the perineum extending to the retroperitoneal tissues. Two survived, probably because adequate debridement was possible.

The role of early radical surgical treatment is confirmed as the most important factor affecting outcome. Response to the initial operation might be of prognostic value.

Early discharge from hospital after open appendicectomy

S. Ramesh and R. B. Galland

Department of Surgery, Royal Berkshire Hospital, London Road, Reading RG1 5AN, UK

Correspondence to:
Mr R. B. Galland

A prospective study of 200 consecutive open emergency appendicectomies was carried out. All patients were informed before operation that they would be discharged the following day if possible. The operation was performed through a standard muscle-splitting incision. At the end of the operation the wound was infiltrated with bupivacaine and a diclofenac suppository was given. There were 29 normal, 129 acutely inflamed, six gangrenous and 36 perforated appendices. In all, 147 patients (73·5 per cent) were discharged home within 24 h and reviewed 2 weeks later. Twelve patients had seen their general practitioner, mainly for wound problems (eight) or pain (two). Two others required readmission. Thirty-four patients (23·1 per cent) required no postoperative analgesia; 104 (70·7 per cent) required paracetamol or co-proxamol for $\leqslant 3$ days and nine (6·1 per cent) for >3 days. No patient had a problem directly related to early discharge from hospital. Fifty-three patients (26·5 per cent) were not discharged home early due to peritonitis (36), social reasons (seven), nausea (seven), associated caecal volvulus (one) and pregnancy (two). Early discharge from hospital within 24 h after emergency appendicectomy is safe and has good patient acceptability.

The length of hospital stay for general surgical procedures is steadily declining, although considerable variation exists between one hospital and another[1]. Many elective operations can now be carried out on a day-case basis[2]. With the advent of laparoscopic cholecystectomy and minicholecystectomy, even patients with gallstones can be dealt with on a day-case or short-stay basis[3]. For emergency admissions, however, the decline in hospital stay is less dramatic[4]. It has been claimed that one of the advantages of laparoscopic compared with open appendicectomy is a shorter hospital stay[5,6].

Patients undergoing open appendicectomy often remain in hospital for 3–5 days after operation[1,4,5]. In one study[7], 80 per cent of children with non-perforated appendices were safely discharged within 48 h of operation, although only 3 per cent were allowed home within the first 24 h.

A prospective and consecutive study of emergency open appendicectomy in adults and children has been carried out to assess the safety and feasibility of planned discharge from hospital 24 h after operation.

Patients and methods

All patients were informed before operation of possible discharge home within 24 h provided their clinical condition was satisfactory. A metronidazole suppository was given with the premedication (1 g for adults, 500 mg for children). All patients underwent standard appendicectomy through a muscle-splitting incision under general anaesthesia. Closure of the muscle layers was carried out with an absorbable suture. In the presence of a normal or acutely inflamed appendix, the skin was closed with subcuticular polydioxanone.

At the end of the procedure the wound was infiltrated with 0·25 per cent bupivacaine and a diclofenac suppository given. Intraoperative use of intramuscular opiates and intravenous fluids was left to the discretion of the anaesthetist. Routine use of postoperative intramuscular narcotics and intravenous fluid replacement was avoided whenever possible. Co-proxamol was the analgesic of choice. Patients with gangrenous appendicitis without perforation were given three doses of metronidazole, and those with peritonitis or perforation a therapeutic course of cefuroxime and metronidazole.

No attempt was made to discharge patients with peritonitis or perforation within 24 h. The other patients, with normal, acutely inflamed or gangrenous appendices, who were felt to be suitable for discharge within 24 h, were encouraged to mobilize early. They were allowed oral fluids and diet on full recovery from anaesthesia. Patients were reviewed the next day and allowed home if well.

Patients discharged within 24 h were reviewed 2 weeks later. They were questioned about their general progress, diet and return to normal activity. The nature and duration of oral analgesia required was noted. The wound was examined and any problems such as discharge, bleeding or infection documented. The timing of, and reason for, any visit to their general practitioner (GP) was also noted. Follow-up of patients not discharged within 24 h was left to the discretion of the admitting surgeon.

Results

Of 200 appendicectomies carried out during a 5-month period, 29 appendices (14·5 per cent) were histologically normal, 129 (64·5 per cent) acutely inflamed, six (3·0 per cent) gangrenous and 36 (18·0 per cent) perforated with peritonitis. The operations were performed mainly by surgeons in training: senior house officer, 68; registrar, 127; consultant, five. The patient male:female ratio was 1:1·3.

A total of 147 patients (73·5 per cent) were discharged within 24 h; 53 remained in hospital for >24 h, mainly due to associated peritonitis (*Table 1*). Fifty-five (85 per cent) of 65 children were discharged within 24 h, compared with 92 of 135 adults (68·1 per cent) ($\chi^2 = 6·1$, 1 d.f., $P < 0·02$). This difference was due to the greater likelihood of peritonitis in adults in this series.

Three children and nine adults had seen their GP within the 2-week follow-up period. In ten of the patients this was because of wound problems (discharge, eight; pain, two). Seven of these wounds had a serosanguineous discharge when seen by the GP and two patients were prescribed a course of antibiotics with good resolution. One patient had a wound abscess following removal of a gangrenous appendix, and required readmission and drainage. All the wound problems developed 7–10 days after operation.

Readmission was required in four of the 200 patients. Two of these had been discharged within 24 h; one was the patient with a wound abscess and the other was readmitted with pyrexia and malaise with a suspected pelvic abscess. Examination under anaesthesia and pelvic ultrasonography did not confirm the abscess, and the patient's symptoms improved on conservative

treatment. At the original operation the appendix was normal and large mesenteric nodes had been found.

Thirty-four patients (23·1 per cent) required no analgesia at home. Paracetamol or co-proxamol was required in 104 (70·7 per cent) for ≤ 3 days and in nine (6·1 per cent) for > 3 days. Analgesia requirements were generally lower, but not significantly so, in children compared with adults. The median time taken for patients to resume normal activities was 3 (range 2–7) days and the time to return to work or school was 7 (range 5–14) days. The 53 patients who were not discharged within 24 h stayed in hospital for a median of 3 (range 2–8) days.

Discussion

If patients undergoing laparoscopic cholecystectomy, or even minicholecystectomy, can be discharged from hospital within 24 h of operation, the same principles should apply to uncomplicated appendicectomy. The present results confirm that 90 per cent of patients undergoing emergency appendicectomy without evidence of peritonitis can be discharged within 24 h, whether adults or children.

A careful explanation was given to the patients before operation so that they knew early discharge from hospital was a possibility. Most of the patients and their relatives accepted the concept readily. Following discharge, analgesia requirements were minimal, and virtually all patients had resumed normal activity at the time of follow-up.

The commonest problem likely to be encountered after appendicectomy is infection within the wound. The use of prophylactic antibiotics in the presence of minimal wound contamination can reduce the incidence of this complication to low levels[8]. Eight patients in this series probably had wound infection, one requiring readmission to hospital. Even with a postoperative stay of between 3 and 5 days, most wound infections become apparent only after discharge from hospital. All the wound problems in this series occurred 7–10 days after operation. No morbidity was encountered as a result of early discharge from hospital. Reported readmission rates after appendicectomy are surprisingly high[7]. It was encouraging to find that only two of the 147 patients in the present series who were discharged early required readmission. In one of these, the admission was almost certainly due to further pain from mesenteric adenitis.

These results confirm that early discharge from hospital after emergency appendicectomy has good patient acceptability and provides little extra work for GPs. A number of advantages of laparoscopic compared with conventional appendicectomy have been described[5,6]. These include lower morbidity, a shorter hospital stay and a quicker return to normal activity. If trials comparing the two techniques are to be organized, then the conventional limb of the trial should include patients managed as described in this paper.

Synchronous abdominoperineal resection without transfusion

L. de Cannière, A. Rosière and L. A. Michel

Surgical Service, Mont-Godinne University Hospital and Department of Surgery, University of Louvain Medical School, B-5530 Yvoir, Belgium

Correspondence to:
Dr L. A. Michel

Blood loss and hypovolaemic shock affect the immune system significantly, and perioperative blood transfusion has been shown to be associated with a higher rate of tumour recurrence in patients with cancer and increased susceptibility to infectious complications. Data obtained from patients undergoing synchronous abdominoperineal excision of the rectum were analysed to assess whether such surgery is feasible without transfusion. Twenty-two consecutive unselected patients were studied. There were 16 men and six women of median age 66 (range 48–80) years. The tumour stage was Dukes' B in 11 patients and Dukes' C in 11. Six patients were severely obese according to body mass index. Four patients required blood transfusion (1, 1, 2 and 2 units). There was no hospital mortality and all perineal wounds healed primarily with no wound infection. Fifteen patients received radiation therapy 6 weeks after surgery. Abdominoperineal resection with minimal blood transfusion is feasible in unselected patients.

Blood transfusion may be a significant factor affecting the function of the immune system after operation and leading to an increased susceptibility to infection[1,2] and multiple organ failure. In patients with cancer the immunosuppressive action of transfusion may be deleterious. Some have reported increased recurrence and decreased survival rates in patients with colorectal[3] and breast[4] cancer. Blood loss and hypovolaemic shock affect the immune system[5], and hypovolaemic events significantly enhance tumour growth, independent of blood transfusion[6].

Other deleterious effects of transfusion during surgery are related to the potential risk of transmission of human immunodeficiency virus (HIV) 1 or hepatitis B and C viruses.

From 1983 to 1991 a prospective study was carried out to examine the feasibility of performing synchronous combined abdominoperineal excision of the rectum without blood transfusion.

Patients and methods

Between September 1983 and October 1991, 22 consecutive unselected patients (16 men, six women) underwent synchronous combined abdominoperineal excision of the rectum. All patients had rectal cancer located 0–7 cm from the anal verge. The mean age was 65 (median 66; range 48–80) years. The preoperative condition of each patient was assessed using the American Society of Anesthesiologists (ASA) classification[7].

A final decision to perform abdominoperineal resection was made at surgery when low anterior resection could not be performed safely or because of bulky local extension of the tumour. The 22 patients represented 16 per cent of a total of 139 with rectal cancer operated on during the study period. The remaining 117 patients underwent anterior resection of the rectum.

The body mass index (BMI; weight (kg)/height^2 (m^2)) was calculated[8] for each patient.

Complete closure of the pelvic peritoneum was performed by the abdominal operator after careful inspection of the sacral concavity for all remaining bleeding points. The perineal operator sutured the levator ani muscles in the midline, as well as fat and skin. The sacral concavity below the pelvic peritoneum was drained by two 19-Fr suction drains through separate stab wounds. All patients received broad-spectrum antibiotic therapy from the day of surgery, ending on day 4 after operation.

Results

Physical status and pathological staging

Sixteen patients were classified as ASA grade II, four as ASA III and two as ASA IV. Fourteen patients (*Table 1*) were considered to be moderately to severely obese at the time of surgery. Eleven patients had Dukes' B tumours and 11 Dukes' C (C_1 in ten, C_2 in one).

Postoperative complications and mortality

Morbidity was related mainly to intermittent urinary problems in elderly men with prostatic hypertrophy (urinary tract infection, one; retention, six). Primary healing of the perineal wound was obtained in all patients. The mean duration of hospital stay was 19 (median 20; range 10–37) days. One patient had a pulmonary embolus, but there were no other complications and no deaths. At 6 weeks after surgery, 15 patients received pelvic external-beam radiation therapy because of extensive rectal tumour invasion of the anal sphincters. A total dose of 45–50 Gy was administered at a rate of 9–10 Gy per week.

Blood transfusion, hypotensive episodes and drainage volumes

No patient developed intraoperative hypotension and only four received perioperative transfusion. Anaemia, related to the cancer, was the reason for preoperative transfusion in two patients (with haemoglobin levels of 4·8 and 5·0 mmol/l), who both received 2 units packed red cells. The two other patients who underwent transfusion had preoperative haemoglobin levels of 6·2 and 6·0 mmol/l, and a level of 5·5 mmol/l on day 1 after operation. They were admitted to the intensive care unit because they were ASA grade III and had ischaemic heart disease. Both received 1 unit packed red cells as a routine order

Table 1 *Body mass index before operation in 22 patients*

Grade	Body mass index (kg/m^2)	No. of patients
0 (normal)	20·0–24·9	8
I (moderately obese)	25·0–29·9	8
II (severely obese)	30·0–40·0	6

Presented at Eurosurgery '92 in Brussels, Belgium, June 1992 and published in abstract form as Br J Surg *1992;* **79**: *S31*

0007-1323/93/091194-02 © 1993 Butterworth-Heinemann Ltd

from the coronary intensive care unit team. The remaining 18 patients, who did not undergo transfusion, had a mean preoperative haemoglobin level of 7·8 (median 8·0; range 6·4–9·0) mmol/l. At discharge the mean level was 7·2 (median 7·4; range 6·2–8·0) mmol/l. Meticulous control of all bleeding points and careful surgical dissection enabled blood loss to be kept to a minimum without increasing the length of surgery. The mean duration of surgery was 270 (median 240; range 200–420) min. The total volume of drainage fluid was recorded for each patient (mean 220 (median 320; range 125–400) ml). The mean duration of perineal drainage was 4 (range 3–5) days. The volume of drainage fluid for the four patients who underwent transfusion was 130, 150, 200 and 260 ml.

Discussion

Synchronous combined abdominoperineal excision of the rectum for tumours located 0–7 cm from the anal verge was the standard operation for most surgeons[9]. Despite current use of sphincter-saving operations, combined excision of the rectum is an important operative treatment for very low tumours[9]. This type of resection leaves a large perineal wound that can be slow to heal if primary closure has been impossible or considered unsafe. The synchronous approach may be more traumatic than other types of rectal excision, because the total surgical trauma is inflicted in a shorter length of time in two surgical areas. Provided the synchronous method is practised under good conditions by fully trained surgeons it is possible to obtain primary healing of the perineal wound. It is also possible to perform an almost bloodless operation and to avoid blood transfusion. Positioning of the patient in the lithotomy–Trendelenburg position with Lloyd-Davies' leg rests offers a satisfactory approach for the abdominal and perineal dissections, even in overweight patients. None of the six severely obese patients (BMI $\geqslant 30\,\mathrm{kg/m^2}$) in this series required transfusion.

Blood transfusion during and after surgery in patients undergoing elective colorectal procedures is followed by infection in 23 per cent of cases[2]. Others have shown that, in patients with various malignancies[3,4], there is a higher rate of tumour recurrence in those who received blood transfusion. These findings are not uniformly observed[10], and a more recent study[5] has shown that the most significant single factor affecting recurrence rate is the number of hypotensive episodes during the operative procedure. Whichever is the most detrimental variable (blood loss, blood transfusion, hypotensive episodes, or all three), the surgeon must try to avoid all of them.

There are theoretical potential risks of infecting the patient with HIV-1 or hepatitis B and C viruses transmitted by blood transfusion. Such a risk should be sufficient to stimulate surgeons to perform bloodless operations.

These results demonstrate that extensive abdominoperineal resection with minimal transfusion can be performed in unselected patients with low rectal tumours.

In a randomized controlled study of 411 patients undergoing elective colorectal surgery, the efficacy and safety of two different regimens of imipenem were compared with those of a control regimen of cefuroxime plus metronidazole. Surgical infections occurred in 92 (26·4 per cent) of 349 evaluable patients. There were no major differences between the three treatment groups. It is concluded that imipenem is as effective as cefuroxime plus metronidazole in the prevention of sepsis after elective colorectal procedures.

The need to provide antibacterial prophylaxis against aerobic and anaerobic organisms in patients undergoing elective colorectal surgery is well established. Of the methods available, the use of perioperative systemic antibiotics combined with mechanical bowel preparation is widely accepted, particularly in the UK.

The development of carbapenem antibiotics with their extremely broad spectrum of antimicrobial activity provides the opportunity of using a single agent in a variety of situations where combination therapy would otherwise be indicated[1]. This study investigated the use of the antibiotic imipenem for perioperative prophylaxis in elective colorectal surgery, and compared it with the widely used combination of cefuroxime plus metronidazole given over a 24-h period. In addition to a course of imipenem given for a similar perioperative period, a short-course regimen of this drug was also investigated in a three-way randomized controlled study.

Patients and methods

Consecutive patients over the age of 18 years undergoing elective colorectal surgery were deemed eligible for entry into the study, provided that they were not pregnant and had no known allergy to any study drug, no concomitant infection, serious comorbidity or inflammatory bowel disease. Patients who had been treated with antibiotics in the preceding 72 h or who had received steroids, antineoplastic agents or radiotherapy before surgery were also excluded. The study was approved by the local hospital ethics committees.

After giving informed consent, patients were randomly allocated to one of three perioperative regimens. Group 1 received imipenem 1 g at induction of anaesthesia with a single further dose of imipenem 1 g at 3 h after surgery. Group 2 received imipenem 1 g at induction of anaesthesia with a subsequent dose of imipenem 1 g at 3 h after operation and a further two doses of imipenem 500 mg at 8 and 16 h. Group 3 received cefuroxime 1·5 g plus metronidazole 500 mg at induction of anaesthesia and further doses of cefuroxime 0·75 g plus metronidazole 500 mg at 8 and 16 h after surgery. All antibiotics were given intravenously.

A complete medical history was taken and an assessment of nutritional status recorded. Criteria used in this assessment were[2]: weight outside the range 90–110 per cent of ideal for height; upper-arm muscle circumference and/or forearm circumference <85 per cent of normal; grip strength <85 per cent of normal; and serum albumin level <32 g/l.

Variables recorded during the operation included duration of the procedure, residual faecal load in the bowel and an assessment of faecal contamination of the peritoneum. The use of antiseptic lavage was left to the discretion of the operating surgeon. Peritoneal and wound swabs were taken for aerobic and anaerobic culture. All susceptibility testing was conducted using disc diffusion methods.

Patients were examined daily for at least 1 week for signs and symptoms of infection. Because of the insidious nature of some postoperative infections, patients were re-examined 6–8 weeks after surgery. When an infection was suspected, appropriate specimens were taken for microbiological culture. Infections were considered to be directly related to surgery if a purulent discharge from the wound occurred, a positive bacteriological culture was obtained, or a deep abscess developed at the site of operation. Similarly, the presence of intra-abdominal abscess, septicaemia or peritonitis was recorded. Wound or anastomotic dehiscence was not considered to be a primary infectious complication: infection resulting from such dehiscence was not therefore counted in the analysis. Other infectious morbidity not so directly related to surgery was also documented.

In the design of the study it was decided that halving the postoperative infection rate would be clinically significant; this premise determined the size of the trial. To detect a reduction of the infection rate from 30 to 15 per cent, 118 patients were required in each treatment group ($\alpha = 0·05$, $\beta = 0·2$).

Comparison of proportions between groups was performed using the χ^2 test. Other comparisons were made through the 95 per cent confidence interval (c.i.).

Results

A total of 411 patients were entered into the study. Of these, 349 were ultimately deemed to be fully evaluable. Reasons why patients could not be evaluated were the finding of non-colonic pathology at laparotomy (27 cases), discovery of established sepsis (13), incorrect allocation (eight), administration of additional perioperative antibiotics (seven), delayed wound closure (four), reoperation required within 72 h (three) and death within 48 h (two).

Patients in the three treatment groups were well matched for age, sex, intraoperative diagnosis and preoperative

nutritional status (*Tables 1* and *2*). Other possible prognostic factors, such as faecal contamination, faecal residue in the bowel and experience of the surgeon, were also recorded and were similar for the three groups. There were minor differences in the type of surgical procedure performed, with a preponderance of right hemicolectomy in group 1 and comparatively few low anterior resections in group 3 (*Table 2*). These differences were not significant and did not affect the results of the study. Patients who received antiseptic lavage were matched for age, sex and diagnosis with those not receiving lavage. As no differences were found in the incidence of postoperative complications between these groups, this factor was not considered further.

After surgery, 54 patients (47·8 per cent (95 per cent c.i. 38·6–57·0 per cent)) in group 1, 63 patients (55·3 per cent (95 per cent c.i. 46·1–64·4 per cent)) in group 2 and 57 patients (46·7 per cent (95 per cent c.i. 37·9–55·6 per cent)) in group 3 were free from infection (*Table 3*). The remainder had either infections related to surgery, non-surgical infections, or both. There were no significant differences between the three treatment regimens in their ability to prevent infection (*Table 4*), either overall ($\chi^2 = 2{\cdot}01$, 2 d.f., $P > 0{\cdot}05$) or for infections clearly related to surgery ($\chi^2 = 3{\cdot}34$, 2 d.f., $P > 0{\cdot}05$).

The duration of hospital stay for patients in each treatment group was recorded. No differences in median (interquartile range) stay were found: group 1, 13 (10–16) days; group 2, 13 (10–17) days; and group 3, 13 (10–18) days.

The pathogens isolated after surgery from the clearly surgical infections are shown in *Table 5*. These data include all the significant bacterial isolates grown from the first specimen from each site, but not isolates from the same site obtained on subsequent days. Similar numbers of bacteria were isolated from each treatment group. There was, however, a significantly different distribution of aerobic and anaerobic isolates detected between the three groups ($\chi^2 = 7{\cdot}19$, 2 d.f., $P < 0{\cdot}05$). Anaerobes were cultured from 12, 15 and six patients in groups 1, 2 and 3, respectively, although these differences were not statistically significant ($\chi^2 = 4{\cdot}94$, 2 d.f., $P > 0{\cdot}05$). All isolates from surgical infection sites in groups 1 and 2 were susceptible to imipenem. Three isolates (two *Pseudomonas* spp., one *Proteus vulgaris*) in group 3 were found to be resistant to cefuroxime. A number of isolates in each treatment group were not susceptibility tested. The minimum time that elapsed before the isolation of bacteria was 2 days in groups 1 and 3, and 3 days in group 2.

Adverse events thought to be possibly related to the study drug were recorded in two patients in group 1 (phlebitis), five in group 2 (two hypotension, one each of phlebitis, rash and erythema) and three in group 3 (diarrhoea). All patients recovered spontaneously from these events.

Discussion

Patients in the control group receiving cefuroxime plus metronidazole (group 3) suffered a surgical 'sepsis rate' of 29·5 per cent. Given this, the power of the study to detect a reduction of 15 per cent was 80 per cent at a significance level of 5 per cent. It is clear from this that both regimens of imipenem provided equivalent protection to that afforded by the triple-dose therapy of cefuroxime plus metronidazole. It is particularly interesting to see that the efficacy of the short two-dose course of imipenem appeared to be as effective as 24 h of prophylaxis with cefuroxime–metronidazole or imipenem. There were no obvious differences between the two imipenem regimens in the proportion of patients developing a postoperative infection, the type of infection nor the duration of hospital stay. This is further evidence supporting the use of short-course prophylaxis in non-contaminated patients undergoing elective colorectal surgery[3,4].

It must be emphasized, however, that such short-course prophylaxis may not prove optimal if significant contamination should inadvertently occur at operation, or if there is established sepsis already present. In this study care was taken to exclude patients with such established sepsis, and also those with inflammatory bowel disease. Similarly, patients were withdrawn from the study if unsuspected sepsis was discovered at laparotomy. Therefore, despite the encouraging results of this study, caution must be exercised before advocating short-course prophylaxis for all colorectal procedures.

More aerobic isolates were obtained from patients in group 3 than in the imipenem groups (1 and 2). In addition, a greater diversity of anaerobic organisms was isolated from the imipenem groups, even though the proportion of patients who subsequently developed anaerobic infection was similar. The *in vitro* antianaerobic spectra of activity of imipenem and metronidazole are similar with few, if any, isolates being resistant to either drug. On the other hand, imipenem has a broader spectrum of antiaerobic activity than cefuroxime, particularly against *Pseudomonas aeruginosa*, *Enterobacter* spp. and the enterococci. Despite this, the number of isolates in this study resistant to any antibiotic was small. It seems unlikely, therefore, that any differences in the *in vitro* spectra were responsible for the clinical dissimilarity. These apparent differences are more likely to be artefacts caused by the low number of patients with isolates and are probably not of clinical significance.

Effect of putative phospholipase A_2 inhibitors on acetic acid-induced acute colitis in the rat

Phospholipase activation may play an important role in ulcerative colitis. This hypothesis was tested by evaluating the effect of two non-selective phospholipase (PL) A_2 inhibitors, quinacrine and p-*bromophenacylbromide (pBPB), on acetic acid-induced colitis in the rat. The calcium antagonist verapamil, which may also act as a PLA_2 inhibitor, was also tested. Acute colitis was induced in an isolated colonic segment by instillation of 4 per cent acetic acid for 15 s; this induces a uniform colitis after 4 days. The severity of colitis was evaluated histologically, by measuring myeloperoxidase (MPO) activity and by determining plasma exudation into the lumen of the colon (permeability) with ^{125}I-labelled albumin given intravenously. All three putative PLA_2 inhibitors tested were found to prevent the development of colitis. Intravenous administration of quinacrine 10 mg kg^{-1} at 30 min before instillation of acetic acid resulted in a normal mucosal appearance, normal MPO activity and a significantly reduced increase in plasma exudation into the colon. A similar effect was achieved using verapamil. Intracolonic administration of either quinacrine or pBPB also prevented acetic acid-induced colitis. However, three doses, starting immediately after acetic acid administration and repeated on the first and second days, were needed to achieve this, whereas one dose produced only a partial effect. PLA_2 may play an important role in acetic acid-induced colitis and inhibition of its activity may offer an alternative mode of treatment in ulcerative colitis.*

Dr R. Fabia

The pathogenesis of ulcerative colitis is largely unknown, although oxygen free radicals and products of phospholipase activation have been suggested to play an important role[1–3]. When oxygen free radicals are generated, they initiate a chain reaction in membrane-bound lipids that leads to lipid peroxidation and consequent activation of phospholipase (PL) A_2[4,5]. Furthermore, oxygen free radicals may induce Ca^{2+} influx into cells, which could then activate several calcium-dependent enzymes[6], including PLA_2. Activated PLA_2 acts on the membrane phospholipids to release arachidonic acid, the precursor of several inflammatory mediators[7,8]. Moreover, PLA_2 might be involved in the initiation of a cascade that generates a variety of bioactive and potentially noxious products, including arachidonic acid metabolites, lysophospholipids and platelet-activating factor[9,10]. This suggests that inhibition of this cascade, either by scavenging oxygen free radicals or by inhibiting PLA_2, could be an effective treatment of ulcerative colitis. Several studies have shown that oxygen free radical scavengers are effective in the treatment of experimental acetic acid-induced colitis in the rat[2,11]. Furthermore, the efficacy of one of the most commonly used drugs in ulcerative colitis, 5-aminosalicylic acid, has been considered to be due partly to its antioxidant properties[12,13]. However, there seem to be no data on the potential effect of PLA_2 inhibitors in the treatment of ulcerative colitis.

It has been shown[14] that acetic acid at a concentration of 4 per cent administered for 15 s into an isolated rat colonic segment induces a uniform acute colitis on day 4 after acetic acid instillation, and that the colitis resolves spontaneously after 14 days. In the present study, the same model was used to investigate the therapeutic effect of two PLA_2 inhibitors, quinacrine and *p*-bromophenacylbromide (pBPB), and the calcium antagonist verapamil[15]. These effects were evaluated by changes in colonic morphology, myeloperoxidase (MPO) activity of the same tissue, and plasma exudation into the lumen of the colonic segment.

Materials and methods

Animals

Female Sprague–Dawley rats weighing 230–250 g were purchased (Møllegaard, Ejby, Denmark) and fed on a standard pellet diet with tap water *ad libitum* before and after surgery.

Surgical procedure

The surgical procedure has been described in detail previously[14]. In brief, a midline laparotomy was performed under ether anaesthesia. The caecum, ascending colon and proximal third of the transverse colon were isolated and the ends brought out through two colostomies with an intact blood supply. Gastrointestinal continuity was re-established using an ileocolic anastomosis. The isolated colonic segment was washed several times with warm (37°C) normal saline. Colitis was induced in the isolated colonic segment by instillation of 4 per cent acetic acid solution for 15 s with a volume (8–10 ml) matching that of the segment. At the end of the exposure to acetic acid, the colonic segment was rinsed three times with the same volume of warm normal saline. Control normal rats were surgically prepared in the same manner but received normal saline instead of acetic acid.

Experimental design

After surgical preparation, 96 rats were divided into eight equal groups. Group 1 consisted of control normal rats (surgically prepared without acetic acid administration) and group 2 of control colitis animals (surgically prepared with acetic acid administration). Both control groups were then treated with normal saline. In groups 3–8, rats had colitis induced as in group 2, but were treated with quinacrine 10 mg kg^{-1} intravenously (group 3), quinacrine locally with one dose of 5 mg per rat (5 ml of 1 mg ml^{-1}, group 4) or with three doses (group 5), pBPB locally using one dose of 5 mg per rat (5 ml of 1 mg ml^{-1}, group 6) or three doses (group 7), or verapamil 0·1 mg kg^{-1}

0007-1323/93/091199-06 © 1993 Butterworth-Heinemann Ltd

intravenously (group 8). (Reagents were purchased from Sigma Chemicals, St Louis, Missouri, USA.) Intravenous treatment was given 30 min before acetic acid administration; local treatment was either administered as a single dose immediately after acetic acid instillation or repeated on the first and second days after surgery (three doses).

Histological examination

Six rats from each group were killed on day 4 after operation by an overdose of ether. The isolated segment of colon was divided longitudinally into two parts, one for histological examination and one for measurement of MPO activity. The part for histological examination was fixed in neutral phosphate-buffered 4 per cent formalin. Ten transverse 4–5-μm slices were taken from different sites along the whole length of the isolated colon in each rat. The slices were stained with haematoxylin and eosin, examined using light microscopy and scored in ignorance of the treatment given. A scale was used[14] to determine the extent of inflammatory reaction in the colonic mucosa. Each of the eight measurements estimated was graded from 0 to 3 depending on the severity of changes found (0, none; 1, mild; 2, moderate; 3, severe). The total score for each animal (maximum 24) was calculated. The features assessed were ulceration, mucus cell depletion, crypt abscesses, inflammatory cysts, mucosal atrophy, oedema, inflammatory cell infiltration and vessel dilatation.

Myeloperoxidase activity

The remaining half of the colonic segment was further divided longitudinally into two parts, one for measuring MPO activity, the other for measuring the dry weight:wet weight ratio. MPO activity was determined by a slightly modified method of Grisham *et al.*[16] in which the enzyme catalyses the oxidation of 3,3′,5,5′-tetramethylbenzidine by hydrogen peroxide to yield a blue chromogen with a wavelength maximum at 655 nm. By definition, 1 unit of enzyme activity produced a change in absorbance per minute of 1·0 at 37°C, expressed as units per gram dry weight.

Plasma exudation into the colonic lumen

Increased mucosal permeability for large molecules was estimated by plasma exudation into the lumen of the isolated segment of colon. This served as an index of acetic acid-induced inflammation.

On the fourth day after surgical preparation and the instillation of acetic acid or normal saline, 48 rats were anaesthetized with ether. The body temperature was maintained at 37°C using a heating pad controlled by a rectal thermistor. The right femoral vein and artery were cannulated. The isolated part of the colon was then cannulated through the colostomy apertures using Silastic (Dow Corning, Midland, Michigan, USA) catheters of internal diameter 3 mm. The plasma tracer, ^{125}I-labelled albumin (Isotoplaboratoriene, Kjeller, Norway) in a volume of 0·1 ml (activity 0·4 MBq), was injected intravenously. Blood samples from the femoral artery were taken 15 min after injection of radiolabelled albumin for determination of the plasma tracer concentration. The isolated colonic segment was perfused intermittently (5 ml every 5 min) through the upper colostomy aperture with warm (37°C) Krebs buffer solution for 30 min. The washed-out solution was collected every 5 min from the lower colostomy aperture and each aliquot measured individually in a γ counter. The total radioactivity of the six samples was then calculated. At the end of 30 min the rats were killed by an overdose of ether and the isolated colon resected for measurement of dry weight. Mucosal permeability was expressed as plasma equivalents in microlitres per minute per gram dry weight for the 30-min period.

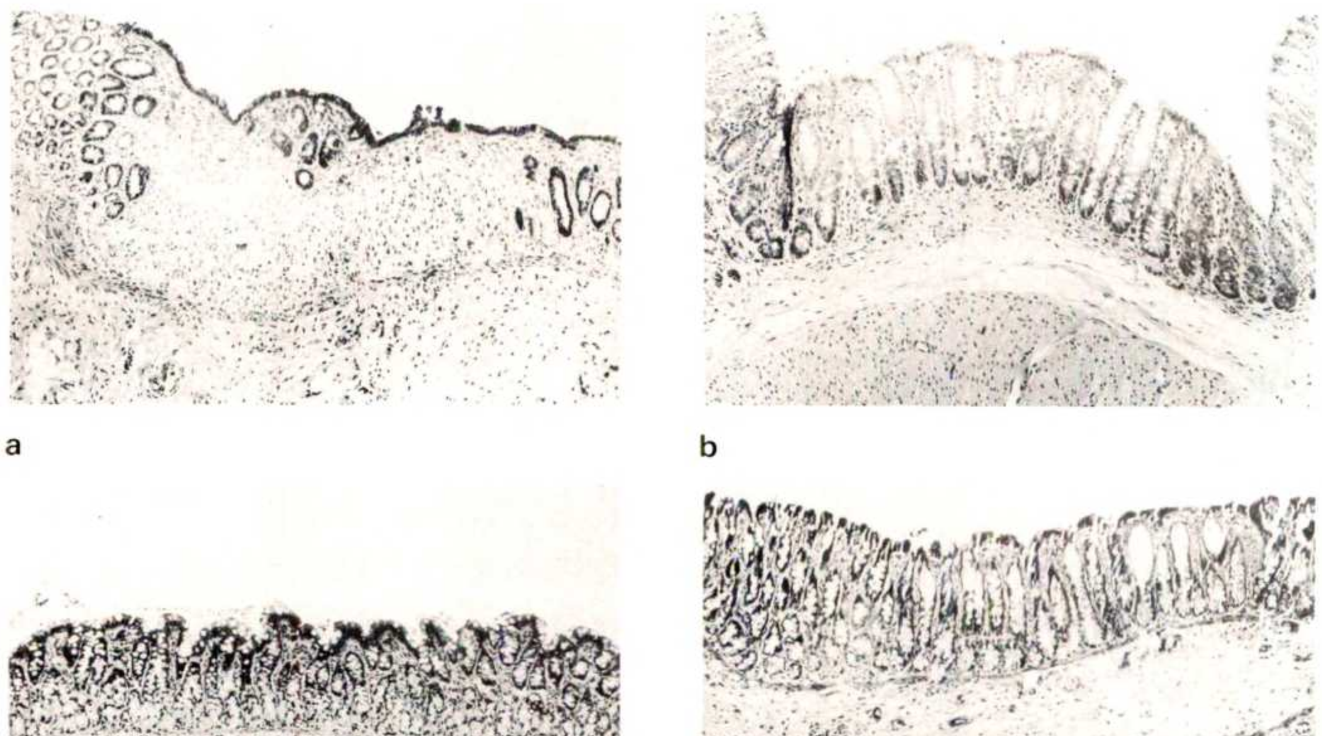

Figure 1 *Photomicrographs showing changes in the colonic mucosa on the fourth day after surgery and acetic acid instillation, except for control normal rats, which received normal saline.* **a** *Control colitis rat. Moderate ulceration, disappearance of glands with mucus cell depletion, cyst formation, moderate inflammatory cell infiltration, oedema and vessel dilatation in the submucosa are visible.* **b** *Control normal rat. Normal mucosa with absence of ulceration and inflammation, substantial mucin production within the glands and slight oedema in the submucosa are seen.* **c** *Rat treated with intravenous quinacrine. Well preserved mucosa with absence of ulceration, minor inflammatory cell infiltration, mucin atrophy and mild oedema in the submucosa are visible.* **d** *Rat treated with intravenous verapamil. Mucosa without ulceration, minor inflammatory cell infiltration, dilated glands with cyst formation, mucin atrophy, mild oedema and moderate vessel dilatation in the submucosa are visible. Statistical analysis

The Wilcoxon rank sum test was used for comparison of histological scores. Student's *t* test was used for analysis of MPO activity and plasma exudation. The relationship between morphological score for inflammatory cell infiltration and MPO activity in the colonic tissue was analysed by linear regression. The relationship between the total morphological score and different doses of locally applied treatment was tested using Spearman's rank correlation coefficient. Results are considered significant at $P < 0·05$.

Results

Histopathological examination

Administration of 4 per cent acetic acid into the isolated colonic segment resulted in uniform colitis as evaluated on the fourth day, with mild to moderate signs of ulceration, inflammatory cell infiltration, oedema, crypt abscesses, cysts and dilated vessels and a mean(s.e.m.) morphological score of 15·7(0·4) (*Figure 1a*; *Table 1*). In contrast, control normal rats without acetic acid administration had slight oedema and sometimes dilated vessels, the mean(s.e.m.) score being 1·7(0·3) (*Figure 1b*).

Rats treated with intravenous quinacrine appeared to have an almost normal mucosa with no sign of ulceration, and a significantly lower mean morphological score than control colitis rats (*Table 1; Figure 1c*). Local treatment with one dose of quinacrine produced partial mucosal preservation with no sign of ulceration (*Table 1; Figure 2a*). Repeated local treatment for 3 days further improved mucosal preservation, although this was not significantly different from that seen after intravenous treatment (*Table 1; Figure 2b*). The dose–response relationship for the two local-dose regimens of quinacrine was highly significant. Similar results were achieved after local treatment with pBPB (*Table 1; Figure 2c* and *d*). The dose–response relationship for the two local-dose regimens of pBPB was again highly significant. Intravenous treatment with verapamil gave a similar result to that with intravenous quinacrine (*Figure 1d*).

Myeloperoxidase activity

MPO activity (*Table 1*) was significantly higher on the fourth day after acetic acid administration in control colitis rats than in control normal animals. Treatment with quinacrine, pBPB or verapamil significantly decreased MPO activity compared with the control colitis group. After intravenous treatment with quinacrine or verapamil, MPO activity was completely normal. Local treatment with one dose of quinacrine or pBPB also decreased MPO activity, although the level remained significantly higher than in control normal rats. Local administration of three doses of quinacrine or pBPB further decreased MPO activity to near-normal levels. The morphological score for inflammatory cell infiltration correlated with MPO activity ($n = 48$, $r = 0{\cdot}897$, $P < 0{\cdot}001$).

Plasma exudation into the colonic lumen

On the fourth day after acetic acid administration, plasma exudation into the colon increased in control colitis compared with control normal rats (*Table 1*). Treatment with quinacrine, pBPB or verapamil significantly reduced plasma exudation compared with control colitis animals, although it remained significantly higher than in control normal rats (*Table 1*).

Discussion

These results show a high efficacy of putative PLA_2 inhibitors in preventing the development of acetic acid-induced colitis. Since there is no known specific PLA_2 inhibitor, three drugs reported to inhibit PLA_2 activity in different ways were used. Quinacrine, an antimalarial agent, affects the enzyme–substrate interface, pBPB covalently binds to the active site of PLA_2, and verapamil reduces the intracellular level of calcium, which is necessary for activation of the enzyme[15]. All three agents were found to be effective in preventing the development of colitis, as demonstrated by histological score, MPO activity and plasma exudation into the lumen of the colonic segment.

MPO is an enzyme present in neutrophils and, at much lower concentration, in monocytes and macrophages[17]. The level of MPO activity appears to be directly proportional to the number of neutrophils in the inflamed tissue[18]. Therefore, measurement of MPO activity is a sensitive quantitative assay for acute intestinal inflammation[17,18]. In the present study, the morphological score for inflammatory cell infiltration correlated with MPO activity ($r = 0{\cdot}897$, $P < 0{\cdot}001$).

The colonic epithelium provides a selective barrier to the transmucosal exchange of solutes and fluids. Inflammation could disrupt this barrier and result in increased permeability, which is suggested to be involved in the pathogenesis of inflammatory bowel disease (IBD)[19]. Thus, changes in mucosal permeability could also indicate mucosal injury and inflammation. Since exudation of plasma across the colonic mucosa occurs in IBD, and permeability has been suggested to correlate with the extent of disease[20,21], we believe that measurement of plasma exudation into the colonic lumen could be an appropriate method for evaluation of mucosal injury. This view was supported by the present results, as a dose-related effect was seen on plasma exudation as well as on total morphological score and MPO activity.

Despite the obvious difference in aetiology between experimental acetic acid-induced colitis and human ulcerative colitis, these models may be useful in investigating the pathogenesis of ulcerative colitis and studying the events that occur at the time of inflammation. As in human IBD, the pathogenesis of acetic acid-induced colitis is not fully understood[22]. However, pathological changes present in human ulcerative colitis have also been reported to occur in experimental acetic acid-induced colitis, such as altered vascularization[23], increased mucosal permeability[24] with enhancement of systemic uptake of intestinal bacteria[25], and increased arachidonic acid metabolism[12,26,27]. Arachidonic acid metabolism in acetic acid colitis is similar to that in human IBD[27]. This might imply that, although colitis can be triggered by different stimuli, the same inflammatory mediators are effecting the final response. The acetic acid-induced colitis model may therefore be appropriate for studying the effect of PLA_2 inhibitors. The present experimental system of colitis has two advantages over previously described acetic acid colitis models: it eliminates the influence of luminal factors acting on the colonic mucosa and it is standardized and reproducible[14].

By 4 days after acetic acid administration, MPO activity increased threefold and mucosal plasma exudation into the colonic lumen increased eightfold in rats with colitis compared with control normal animals. The fourth day was chosen as the optimal time to evaluate the effect of PLA_2 inhibitors. The morphological scores of the control normal and control colitis groups in the present study (*Table 1*) were close to previous results[14], confirming the reproducibility of the model.

These results show that both systemic and local administration of PLA_2 inhibitors are effective in preventing acetic acid-induced colitis. However, intravenous administration of quinacrine gave better results than local intracolonic administration. The effect of intracolonic administration was also good, but three repeated doses were needed. This might be due to the amount of quinacrine that remained in the isolated colon and was subsequently absorbed into the colonic mucosa to inhibit the enzyme. On the other hand, the superiority of intravenous administration might be due to the timing of drug delivery, 30 min before acetic acid instillation. This could have led to relatively high concentrations of the drug at the time of acetic acid administration, which inhibited the activated enzymes. The plasma half-life of quinacrine in the rat is not known; however, in humans it is about 1 week and in rabbits about 26 h, which suggests that in the rat it would be several hours[28].

Recent findings indicate that PLA_2 activation plays an important role in mediating ischaemic intestinal injury in rats[5]. It has been suggested that similar mechanisms are at least partly responsible for the mucosal inflammation and injury associated with ulcerative colitis[1,2,11]. Histological analysis of mucosal samples from patients with ulcerative colitis has revealed many similarities with mucosa taken after ischaemia-induced intestinal injury[29]. Such similarities may be due to the activity of oxygen free radicals in both ischaemic injury and intestinal inflammatory disease[30].

One of several mechanisms by which oxygen free radicals may injure the intestinal mucosa is lipid peroxidation[6,30,31]. During peroxidic decomposition of the organelle membrane lipids, the activity of PLA_2 increases[32]. Intestinal ischaemia has been found to be connected with increased levels of PLA_2, decreased activity of lysophospholipase, and an increased ratio of lysophosphatidylcholine to phosphatidylcholine[4,5]. Moreover, the intestinal mucosa could be protected from ischaemic injury by the PLA_2 inhibitor quinacrine[4,5]. In fact, quinacrine has been shown to be more effective in preventing mucosal injury than oxygen radical scavengers[4,5]. Since levels of oxygen free radicals have been reported to increase during active ulcerative colitis, their mode of action may be similar to that noted in ischaemic intestinal injury. Thus, lipid oxidation and PLA_2 activation should be expected. PLA_2 is involved in the generation of bioactive and potentially noxious metabolites, such as arachidonic acid metabolites, lysophospholipids and platelet-activating factor[9,10,33]. These metabolites are all known mediators of inflammatory reaction in ulcerative colitis[3,26,34]. The products of both pathways of arachidonic acid metabolism (the cyclo- and lipo-oxygenase pathways), as well as platelet-activating factor and lysophospholipid, have been detected in inflamed mucosa in human and experimental colitis[3,9,17,33–35]. Inhibitors of these metabolites could, at least partly, reduce mucosal injury in ulcerative colitis[36]. Therefore, the inhibition of PLA_2 could be effective in the treatment of ulcerative colitis. This hypothesis is consistent with current evidence[37] suggesting that the anti-inflammatory effect of corticosteroids, the most effective treatment for ulcerative colitis, may be mediated by induction of the synthesis of a peptide (lipocortin) that inhibits PLA_2. Moreover, the importance of PLA_2 activity in ulcerative colitis is supported by a recent clinical study showing correlation between serum levels of the enzyme and the endoscopically determined severity of disease[38].

In summary, three different and non-selective PLA_2 inhibitors prevent acetic acid-induced colitis in the rat as judged by three indices of inflammation: morphological scoring, assay of tissue MPO activity and measurement of plasma exudation into the isolated colon. PLA_2 may play a role in the pathogenesis of acetic acid-induced colitis and inhibition of the enzyme may offer a mode of treatment in ulcerative colitis.

Correspondence to: Mr T. S. O'Brien

Colonic perforation is a recognized complication of colonoscopic biopsy, usually manifesting itself within 72 h of the procedure[1]. A case is reported of delayed colonic perforation 9 weeks after biopsy.

Case report

A 50-year-old man presented acutely with a 3-h history of sudden-onset abdominal pain and vomiting. He had a temperature of 37·8°C and clinical signs of generalized peritonitis. Erect chest radiography showed free air under the left hemidiaphragm. Laparotomy revealed purulent peritonitis arising from a punched-out 4-mm perforation in the anterior wall of the distal third of the sigmoid colon. The perforation was not related to a diverticulum and the colon was otherwise normal. The perforation was biopsied and oversewn. The patient made an uneventful recovery and was discharged on the sixth day after operation.

The patient had 9 weeks previously undergone colonoscopy with 'hot' excision biopsy of an adenomatous polyp at 30 cm. Some 2 weeks later he had been reviewed in the outpatient department and had complained of mild aching in the left iliac fossa but was otherwise well with only minimal abdominal tenderness; no action had been taken.

Histological examination of the biopsy revealed extensive necrosis with mixed acute and chronic inflammatory infiltrates. There was granulation tissue formation and evidence of regenerating epithelium, but no signs of neoplasia.

Discussion

Although minimally invasive and generally effective, colonoscopic polypectomy is associated with a number of complications, the two most common being haemorrhage and perforation. Haemorrhage is more common after removal of large polyps (>2 cm) and may complicate up to 2 per cent of all biopsies[1]. Perforation occurs in 0·1–0·5 per cent of biopsies[1,2] and is usually apparent at the time of biopsy or becomes evident within 72 h as the patient develops signs of peritonitis. The present report is believed to be the first of perforation as a late complication of polypectomy. In this patient no other reason for the perforation could be identified, there being no diverticular disease or other colonic pathology. Histological analysis revealed chronic inflammation at the site of perforation, indicating an established injury. The mechanism of perforation is unclear but may relate to a full-thickness burn at the time of biopsy that initially sealed off before breaking down some weeks later.

Clinicians should not rule out colonoscopic biopsy as a cause of symptoms even several weeks after the procedure. This advice may be of particular relevance given the increasingly conservative approach to the management of colonoscopic perforation[2].

Surgical treatment of multiple endocrine neoplasia-related parathyroid disease

D.S. O'Riordain, T. O'Brien, A. Weaver, H. Gharib, C.S. Grant and J.A. van Heerden, *Department of Surgery and Division of Endocrinology, Mayo Clinic and Mayo Foundation, Rochester, Minnesota, USA*

Opinion on the surgical management of parathyroid disease in multiple endocrine neoplasia (MEN) type I is divided between total parathyroidectomy with autotransplantation and subtotal resection. The rarity of MEN II-related primary hyperparathyroidism has not allowed for a well defined policy for this condition. This study compares subtotal (three or more glands) with more conservative resections for primary hyperparathyroidism in MEN I and IIA.

Reported are 135 consecutive surgical procedures performed in 125 patients for MEN-related parathyroid disease, between 1970 and 1991, at a single institution. In all, 106 patients had MEN I and 19 MEN IIA. Associated endocrinopathies in patients with MEN I were islet cell tumours (40 per cent) and pituitary adenoma (42 per cent), and in MEN IIA medullary thyroid cancer (100 per cent) and phaeochromocytoma (32 per cent). Primary cervical explorations for primary hyperparathyroidism were performed in 103 patients (84 MEN I) and 32 secondary or tertiary procedures were performed in 22 patients with MEN I.

When compared with those with MEN I, patients with MEN IIA had a lower median serum Ca^{2+} level at diagnosis (2·65 *versus* 2·82 mmol l^{-1}), were less frequently symptomatic (21 *versus* 51 per cent), had a lower incidence of renal calculi (16 *versus* 37 per cent) and more frequently had apparent single-gland disease (37 *versus* 20 per cent). In MEN IIA, all patients, whether treated by total ($n = 2$), subtotal ($n = 7$) or lesser ($n = 10$) resection, were cured following surgery and none had recurrence over a median follow-up of 5·6 years. Primary and secondary explorations in MEN I resulted in immediate cure of 79 of 84 and 19 of 22 patients respectively. Of primary MEN I operations, failure of immediate cure occurred in three of 16 cases where fewer than four glands were visualized compared with two of 68 where four or more glands were found ($P < 0·05$), and each of these five failed cases had fewer than three glands excised. Among primary MEN I explorations that resulted in a cure, 10-year recurrence rates (Kaplan–Meier) were 21 per cent overall, 22 per cent for those having subtotal resection and 19 per cent for lesser resection.

Parathyroid disease in MEN I and IIA should be viewed as different disease processes and the principles governing surgery for these conditions should differ. In primary MEN I surgery, the aims should be: (1) identification of at least four glands and excision of supernumerary thymic glands to ensure immediate cure; and (2) subtotal resection to facilitate reoperation in the subgroup for whom the disease will inevitably recur. In MEN IIA the aim is to identify and resect all enlarged glands to ensure cure, but routine subtotal resection is unnecessary as recurrence is rare.

Results of surgical treatment for renal hyperparathyroidism

E. Neonakis, M.H. Wheeler, H. Krishnan, G. Coles*, F. Davies* and J.S. Woodhead†, *Departments of Surgery, *Medicine and †Biochemistry, University Hospital of Wales and Royal Infirmary, Cardiff, UK*

A retrospective analysis of 67 consecutive patients who had undergone parathyroidectomy for hyperparathyroidism secondary to renal failure was carried out. In all, 35 patients were on haemodialysis and 32 had received a renal transplant. Total parathyroidectomy and autotransplantation was performed in 52 patients and subtotal parathyroidectomy in 15.

Indications for surgery were primarily hypercalcaemia, bone disease and high parathyroid hormone levels in patients on haemodialysis and persistent hypercalcaemia after renal allograft in transplant patients.

Symptomatic improvement after parathyroidectomy occurred in 81 per cent of patients on haemodialysis and 72 per cent of those given transplants. The best predictor of successful relief of skeletal pain after parathyroidectomy was a raised preoperative alkaline phosphatase level. Following total parathyroidectomy and autotransplantation, 25 per cent of patients developed severe postoperative hypocalcaemia, in contrast to none after subtotal parathyroidectomy. There was a good correlation ($r = -0·557$, $P < 0·001$) between hypocalcaemia and preoperative alkaline phosphatase levels.

Of surviving patients, four of 38 after total parathyroidectomy and autotransplantation, and one of 14 after subtotal parathyroidectomy developed recurrent hyperparathyroidism. All five patients with recurrent disease were on haemodialysis (22 per cent).

Transplant patients usually present with less severe disease, have better normalization of biochemical parameters after parathyroidectomy and rarely develop recurrent hyperparathyroidism compared with those on haemodialysis. Patients undergoing subtotal parathyroidectomy have a less eventful postoperative course than those treated by total parathyroidectomy and autotransplantation. However, both procedures result in good control of renal hyperparathyroidism with excellent improvement of symptoms.

Parathyroidectomy in chronic renal failure

N. Younis, J. Walls, R.M. Higgins*, M. Venning*, P. Ackrill*, E.N. Gleave and N.J. Bundred, *Departments of Surgery and *Nephrology, University Hospital of South Manchester, Manchester, UK*

The aims of this study were to evaluate preoperative localization techniques and results of parathyroidectomy in patients with chronic renal failure. A retrospective review of 42 patients was made (23 male, 19 female; mean age 43 (range 21–72) years, mean follow-up 55 (range 1–162) months). Thirty-two patients were on haemodialysis, nine were on chronic ambulatory peritoneal dialysis and one had a transplant. Preoperative localization was achieved in 24 patients using computed tomography (CT) and in 22 using technetium-99–thallium-201 subtraction scanning.

In all, 32 patients had four-gland total parathyroidectomy, of whom 24 had parathyroid reimplantation; one patient underwent subtotal parathyroidectomy. In seven patients only three glands were identified and in two only two glands were found; total excision with reimplantation was performed. Four reoperations were performed for recurrent hyperparathyroidism; three ectopic glands were identified in patients previously shown histologically to have had total parathyroidectomy. Eight of ten patients having undergone three-gland excision had persistent hyperparathyroidism and two of 32 of the alive reimplanted patients have recurrent hyperparathyroidism but remain asymptomatic.

Subtraction scanning correctly identified only 29 of 82 (35 per cent) surgically excised parathyroid glands and CT 55 of 90 (61 per cent). Preoperative localization proved unhelpful except at reoperation when 75 per cent of glands were identified. Total parathyroidectomy with or without reimplantation is the treatment of choice in hyperparathyroidism of chronic renal failure.

Successful allotransplantation of microencapsulated parathyroid glands in rats

C. Hasse, I. Schrezenmeier*, B. Stinner, C. Schark, P.K. Wagner, K. Neumann† and M. Rothmund, *Departments of Surgery and †Pathology, Philipps University, Marburg and *III Medical Hospital, Johannes Gutenberg University, Mainz, Germany*

The various roles of parathyroid hormone in metabolism make drug therapy for persistent hypoparathyroidism difficult, but do not justify parathyroid transplantation with immunosuppression. Reduction in immunogenicity of the tissue using culture passages is rarely successful.

0007-1323/93/091205-05 © 1993 Butterworth-Heinemann Ltd

This study examined microencapsulation as a method of immunoprotection while maintaining gland function.

Parathyroidectomy was performed on 280 Lewis and 14 DA rats. After passage in tissue culture for 6 days, 50 per cent of the parathyroid glands of the Lewis rats were microencapsulated, and 10:1 (donor:recipient) isotransplanted ($n = 7$) and allotransplanted ($n = 7$). The other 50 per cent were treated similarly, except for the microencapsulation ($n = 7$ each). Serum calcium levels were tested on the day before parathyroidectomy, and 7 and 14 days afterwards in the donors, and, additionally, every week in the recipients. Successful transplantation was defined as a minimal increase in serum calcium level from $<1{\cdot}6$ to $>1{\cdot}9$ mmol l^{-1}. At 3 months after implantation histological examination was performed on the transplant.

Before the study, all animals were normocalcaemic. After parathyroidectomy, all became hypocalcaemic with a mean serum calcium level of 1·55 mmol l^{-1}. At 6 weeks after transplantation, all isotransplanted and one allotransplanted rat without microencapsulation were normocalcaemic; four isotransplanted and no allotransplanted rats were normocalcaemic after 12 weeks. In the group with microencapsulated transplants, all seven isotransplanted and six allotransplanted rats became normocalcaemic 6 weeks after transplantation and after 4 months four and five respectively were normocalcaemic. Histological examination of functionally successful transplants revealed intact glands or fibrotic remnants of glands. There was no difference in pericapsular lymphocytic and fibroblastic infiltration between isotransplanted and allotransplanted animals.

In an animal experiment, microencapsulated parathyroid tissue, both isografted and allografted, can survive and function in a host. The microcapsule protects the transplant successfully from a foreign-body reaction by the recipient.

Primary hyperaldosteronism cured by unilateral adrenalectomy

C. Proye, J.-C. Martinot, C. Gonzales and B. Carnaille, *Service de Chirurgie Générale et Endocrinienne, Hôpital Huriez, CHU de Lille, Lille, France*

In patients with primary hyperaldosteronism, the surgeon may be reluctant to perform unilateral adrenalectomy if evidence of an adenoma is lacking on imaging studies.

A consecutive series of patients underwent adrenalectomy for proven primary hyperaldosteronism. The efficacy of this procedure as a cure for hypertension and biochemical abnormality was examined.

Between 1970 and 1992, 60 patients underwent surgery for primary hyperaldosteronism. All were hypertensive; five underwent bilateral and 55 unilateral adrenalectomy. The series included 44 macroadenomas ($\geqslant 1$ cm in diameter), nine microadenomas (<1 cm), four associations of macroadenoma and microadenoma, and three cases of unilateral hyperplasia. Tumour pathology was defined in preoperative studies with a sensitivity of 100 per cent for magnetic resonance imaging, 97 per cent for computed tomography, 72 per cent for scintigraphy, 35 per cent for ultrasonography and 100 per cent for venous sampling.

Four of 55 patients remained hypertensive after unilateral adrenalectomy (three of 44 macroadenomas and one of three unilateral hyperplasia) but all had been biochemically cured after surgery. In two the syndrome recurred (two macroadenomas) and one was reoperated on for contralateral multiple 'adenomas'.

Adrenalectomy for unilateral hyperplasia may lead to cure but the syndrome may recur after removal of a solitary macroadenoma. When a firm diagnosis of primary hyperaldosteronism has been made and the unilateral nature of the disease established, the patient should be operated on.

Conn's syndrome: 14 years' experience

M. Puccini, P. Miccoli and J.A. Lynn*, *U.O. Endocrinochirurgia, Clinica Chirurgia, Università di Pisa, Italy and *Department of Surgery, Royal Postgraduate Medical School, London, UK*

Between October 1978 and October 1992, 55 patients were operated on for primary aldosteronism. The mean age was 50 years. The male:female ratio was equal and there was no propensity of lesions to a particular side. Diagnosis was made in all patients on depressed serum potassium levels, raised serum aldosterone and depressed plasma renin. Localization procedures varied during the period, from ultrasonography to iodocholesterol, computed tomography and latterly magnetic resonance imaging, which was particularly useful in patients who were pregnant. Two women presented in pregnancy, one operated on at full term and one at 18 weeks. A posterior approach was used in all patients, with the exception of one with malignant disease and two with concomitant cholecystitis; these patients were treated transabdominally. The pathology consisted of 51 adenomas, one carcinoma, one doubtful hyperplasia or adenoma and two documented hyperplasia.

There were no operative deaths. In 50 of 51 patients with a single adenoma, potassium level and blood pressure returned to normal. In one patient, the serum potassium level was normal but the patient needed antihypertensive agents long term. In this latter patient the aldosterone and renin levels returned to normal. Of two patients with proven hyperplasia, one was cured by unilateral adrenalectomy and the second had normal levels of serum potassium, but blood pressure remained raised and the patient required antihypertensive therapy. The patient with carcinoma died from metastatic disease 4 years after the original adrenalectomy.

With effective localization, single adenoma can be effectively treated by a simple posterior approach with a high cure rate.

Acute Addison's disease after excision of Conn's adenoma

A. Stacey-Clear and A.E. Young, *Directorate of Surgery, St Thomas' Hospital, London, UK*

Primary hyperaldosteronism caused by a solitary adenoma is usually cured by unilateral adrenalectomy. Postoperative supplementation with steroids is not normally considered necessary.

After a 10-year history of poorly controlled hypertension a 44-year-old man was found to be hypokalaemic. His recumbent morning serum aldosterone level was 1·02 pmol l^{-1} and this rose to 1·65 pmol l^{-1} after ambulation. Morning recumbent plasma renin levels were 1312 pmol l^{-1}, 2007 pmol l^{-1} on rising and 3332 pmol l^{-1} by mid-day after ambulation.

Computed tomography showed a 5-cm mass in the left adrenal gland. A diagnosis of primary Conn's syndrome resulting from an adenoma was made and the patient referred for adrenalectomy. After operation the man remained hypertensive and suffered anorexia and weakness, but was well enough to be discharged 7 days after operation.

Some 2 weeks later the man was readmitted in acute renal failure considered to result from acute Addison's disease complicated by infection. At this time histological analysis of the original adrenal specimen showed a cortical adenoma and cortical atrophy. Adrenal antibodies were found. No cause for the adrenal suppression was found and it recovered spontaneously after 6 months.

This patient may have had a tumour producing glucocorticoid in addition to mineralocorticoid. This possibility should be borne in mind when deciding whether postoperative steroid replacement is necessary after unilateral adrenalectomy in Conn's syndrome.

Vascular invasion in adrenal tumours

J. Hamilton, E.A. Sheffield* and J.R. Farndon, *University Departments of Surgery and *Pathology, Bristol Royal Infirmary, Bristol, UK*

Vascular involvement in 11 adrenocortical adenomas, seven cortical carcinomas (defined by large size, weight or metastasis) and 12 phaeochromocytomas was studied. Four cases of nodular hyperplasia and two of diffuse hyperplasia were examined.

Three carcinomas showed invasion of large capsular muscular veins. One patient died from metastases 2 years after diagnosis. Three of the 12 phaeochromocytomas showed invasion of large veins; no metastases have occurred (minimum follow-up 6 months).

If large vein invasion was present, small capsular sinusoidal vessel invasion was also seen. Necrosis and mitoses, but not nuclear pleomorphism, were associated with large vein invasion. Large vein invasion was not identified in other lesions.

Of the four adrenal carcinomas free of large vessel invasion, three showed small vessel involvement. Similarly, of the nine phaeochromocytomas free of large vein invasion, three showed small vessel involvement. Seven of the 11 adenomas showed subcapsular or intracapsular involvement of small vessels. One hyperplastic adrenal showed involvement of small vessels.

This study confirms that invasion of large veins is an associated, but unreliable, feature of malignancy in adrenal tumours. Involvement of smaller vessels is not significant and may be seen in benign lesions; this feature probably reflects the physiological affinity that endocrine cells have for blood vessels, and may create diagnostic difficulty in some situations.

Influence of changing scanning techniques on gland localization in primary hyperparathyroidism

D.A. Browell, J.R. Farndon*, I.D.A. Johnston, G. Proud, A.J. Manouras†, P.J. Kelly‡ and T.W.J. Lennard, *Departments of Surgery and ‡Medical Statistics, University of Newcastle, Newcastle upon Tyne, UK and Departments of Surgery, Universities of *Bristol, UK and †Athens, Greece*

The influence of isotopic and ultrasonographic scans on operating time was studied in a series of parathyroidectomies for primary hyperparathyroidism. Localization by scan, operative findings, gland histology and weight were compared. All procedures were carried out by four consultants or with the consultants assisting senior registrars, using a standard operative strategy, aiming to identify all four glands.

Before the use of regular scanning techniques in 1980 the mean operating time was 108·9 min ($n = 22$). This time was significantly improved to a mean of 85·7 min ($n = 102$) with the introduction of ultrasonography and thallium–iodine subtraction scanning ($P < 0{\cdot}0001$). In 1990, new analysis techniques in radioisotope scanning were introduced and only specified radiologists performed the ultrasonographic scans. Despite this, there has been no overall change in the accuracy of ultrasonography (35·6 *versus* 34·1 per cent; $\chi^2 = 1{\cdot}01$, 2 d.f., $P = 0{\cdot}6$) or radioisotopic localization (58·6 *versus* 53·3 per cent; $\chi^2 = 3{\cdot}54$, 2 d.f., $P = 0{\cdot}17$), with no significant improvement in operating time (mean 81·0 min, $n = 44$). During this period the gland weight has decreased significantly from a mean of 330·0 mg to 194·7 mg ($P = 0{\cdot}024$). An incorrectly localized gland causes an increased operating time (mean(s.d.) 85·5(29·8) min), over a failure of localization (79·4(22·9) min), which was only marginally worse than when both scans localized the gland (78·7(23·4) min).

Magnetic resonance imaging in thyroid swelling

J.S. Bagley, S.W.B. Ewen*, F.W. Smith† and Z.H. Krukowski, *Departments of Surgery, *Pathology and †Nuclear Medicine, Aberdeen Royal Infirmary and University of Aberdeen, Aberdeen, UK*

Current imaging techniques such as isotope scanning, ultrasonography and computed tomography (CT) have a variable but restricted role in the assessment of functionally normal thyroid swellings. Although ultrasonography and CT demonstrate the morphology of the gland, their utility is limited by a low sensitivity for neoplasia[1].

As a preliminary to an assessment of the role of magnetic resonance imaging (MRI) in the management of thyroid swelling, the pathological appearances of a consecutive series of 20 resected thyroid swellings were correlated with the images produced from an MRI scanner using a range of imaging software (Siemens Magnetom Impact 1·0 T with A1.3 software and Power Package enhancement) to determine whether any patterns of image exist that may be useful in differentiating thyroid pathology.

No clear pattern or correlation of MRI images with pathology emerged in this early series.

Influence of inferior thyroid artery ligation on parathyroid function after subtotal thyroidectomy

C. Nies, T. Bandorski, J. Menze, H. Sitter, K. Ehlenz and M. Rothmund, *Department of Surgery, Philipps University, Marburg, Germany*

In most individuals all four parathyroid glands receive their blood supply from the inferior thyroid arteries (ITAs). The influence of ligation of these arteries on postoperative parathyroid function was investigated in patients undergoing bilateral subtotal thyroidectomy for benign multinodular non-toxic goitre.

In a randomized controlled trial, 100 patients undergoing bilateral subtotal resection for benign multinodular non-toxic goitre were divided into two groups of 50 patients. In group 1 the main ITA was ligated and in group 2 the branches of the ITA were suture ligated at the thyroid capsule. Serum total calcium (Ca), ionized calcium (Ca_{ion}) and parathyroid hormone (PTH) levels were determined before operation and 6, 24 and 72 h after operation. Patients were seen for follow-up after a mean of 7 months.

In both groups 11 patients temporarily required calcium substitution for symptomatic hypocalcaemia in the immediate postoperative period. At follow-up no patient in either group was hypocalcaemic.

	Mean(s.d.) serum level				
	Preop.	6 h	24 h	72 h	Follow-up
Ca (mmol l^{-1})					
Group 1	2·33(0·10)	2·09(0·13)	2·11(0·11)	2·18(0·14)	2·32(0·09)
Group 2	2·34(0·07)	2·09(0·13)	2·11(0·14)	2·17(0·19)	2·34(0·09)
Ca_{ion} (mmol l^{-1})					
Group 1	1·23(0·05)	1·16(0·06)	1·13(0·09)	1·17(0·10)	1·21(0·09)
Group 2	1·25(0·06)	1·15(0·07)	1·13(0·08)	1·17(0·09)	1·21(0·04)
PTH (ng ml^{-1})					
Group 1	46(18)	31(19)	33(14)	35(17)	41(22)
Group 2	41(16)	25(13)	29(14)	32(12)	34(13)

Differences between groups 1 and 2 were not statistically significant. It is of no consequence whether the ITAs are ligated in subtotal thyroidectomy for benign multinodular non-toxic goitre.

Role of parathyroid hormone-related protein in the diagnosis of hypercalcaemia in a screened population

J. Walls, W.A. Ratcliffe, S. Hughes, A. Howell and N.J. Bundred, *Departments of Surgery and Oncology, University Hospital of South Manchester, Manchester and Wolfson Research Laboratories, Birmingham, UK*

Parathyroid hormone-related protein (PTHrP) is humorally secreted by malignant tumours. In animal models it has been shown to act on the distal renal tubule to increase reabsorption of calcium via the second messenger cyclic adenosine-3′,5′-monophosphate (cAMP), leading to hypercalcaemia. The diagnostic value of plasma PTHrP levels and its actions on the kidney in humans are unknown but are of great clinical potential.

A screening service for all inpatients with hypercalcaemia was carried out over a 16-month period. Patients had plasma PTHrP and PTH levels measured using two-site immunoradiometric assays. Urine was collected for cAMP and electrolyte measurements. Statistical analysis used the Wilcoxon ranked pairs test and Spearman correlation coefficient (r_S).

In all, 107 patients were screened and a final diagnosis made of 68 with malignancy and 39 with hyperparathyroid disease. Sixty patients with malignancy (88 per cent) had raised plasma PTHrP levels, and in these raised PTHrP correlated with serum calcium ($r_S = 0{\cdot}47$, $P < 0{\cdot}05$), urinary cAMP ($r_S = 0{\cdot}32$, $P < 0{\cdot}05$), and calcium reabsorption ($r_S = 0{\cdot}56$, $P < 0{\cdot}01$). Renal tubular effects seen in patients with raised PTHrP levels were similar to effects in those with parathyroid disease. The use of both assays changed the final diagnosis in ten patients (9 per cent) and therefore improved the differential diagnosis of hypercalcaemia. Although the humoral actions of tumour-derived PTHrP account for hypercalcaemia in the majority of patients with malignancy, hyperparathyroidism should always be excluded.

Reoperation for parathyroid adenoma unsuspected and missed during previous thyroidectomy: lateral *versus* thyrothymic approach

J.F. Henry, A. Denizot, A. Porcelli and J.-F. Bataille, *Department of Endocrine Surgery, University Hospital la Timone, Marseille, France*

Of 760 patients operated on for primary hyperparathyroidism, 18 (2·4 per cent) had undergone one or more previous thyroidectomies. Before thyroid surgery seven of the 18 patients presented with hypercalcaemia that had not justified a concomitant parathyroid exploration. Of these seven patients, five had undergone unilateral lobectomy and two bilateral thyroidectomy for benign lesions. In the postoperative course diagnosis of primary hyperparathyroidism was confirmed. Before parathyroidectomy all patients had non-invasive localization studies that were positive in five cases. The mean time between thyroidectomy and parathyroidectomy was 5 years (range 2 months to 12 years).

Because the adenomas were suspected to be outside the area of the initial operation, and to avoid any dissection in the dense scar tissue and fibrosis, two selective surgical approaches were used for reoperation: a unilateral approach for three adenomas located on the side of the remaining normal thyroid lobe and a thyrothymic approach for four lesions located in the thyrothymic tracts. In all patients the approach allowed visualization of a second gland. All patients were cured of primary hyperparathyroidism. There were no recurrent laryngeal nerve injuries and no hypoparathyroidism.

In conclusion, reoperation for unsuspected and missed parathyroid adenoma during previous thyroidectomy can be performed safely if the surgical approach avoids the area of initial operation. Non-invasive localization studies are justified in these patients. The lateral approach is recommended for superior and the thyrothymic approach for inferior glands.

Hypercalcaemia of malignancy: effect of biphosphonate therapy on parathyroid hormone-related protein and renal tubular function

J. Walls, W.A. Ratcliffe, S. Hughes, A. Howell and N.J. Bundred, *Departments of Surgery and Oncology, University Hospital of South Manchester, Manchester and Wolfson Research Laboratories, Birmingham, UK*

Parathyroid hormone-related protein (PTHrP) is the major humoral factor causing hypercalcaemia of malignancy (HM). In experimental models PTHrP 1-34 interacts with PTH receptors to increase bone resorption and stimulate calcium reabsorption in the distal renal tubule. Thirty-four patients with symptomatic HM were studied and initial parameters of renal tubular function compared with those of 18 patients with primary hyperparathyroidism. Statistical analysis used Wilcoxon ranked pairs and Spearman correlation coefficient.

In HM, levels of plasma PTHrP 1-86 measured by a two-site immunoradiometric assay ranged from 0·23 to 17·8 pmol l^{-1}, and were undetectable (<0·023 pmol l^{-}) in hyperparathyroidism. Urinary cyclic adenosine-3′,5′-monophosphate (cAMP) and calcium excretion were raised in both groups and did not differ significantly.

In HM following intravenous pamidronate 30–60 mg there was a reduction in plasma PTHrP level (median reduction 0·78 pmol l^{-1}, P = 0·007) on days 3–7 when serum calcium reached its nadir, while serum PTH remained suppressed. In HM at presentation, plasma PTHrP correlated with serum calcium (r_S = 0·49, P < 0·05), urinary cAMP (r_S = 0·32, P < 0·05), and calcium excretion (r_S = 0·54, P < 0·01).

The serum calcium level fell to below 2·6 mmol l^{-1} in 24 patients while calcium excretion in the group as a whole showed a median reduction of 138 μmol per litre glomerular filtrate (P < 0·05). In a subgroup of 16 patients with humoral HM (i.e. no bone metastases), seven failed to respond to pamidronate, while only two of 12 patients with proven bone metastases failed to achieve normocalcaemia (P not significant). In conclusion, plasma PTHrP level correlates with renal tubular function, and a fall in plasma PTHrP level and renal tubular calcium reabsorption has been demonstrated in patients following pamidronate therapy.

Safety of the posterior approach in adrenal surgery

C. Proye, J.-Y. Huart, X. Cuvillier, B. Gambardella and B. Carnaille, *Service de Chirurgie Générale et Endocrinienne, Hôpital Huriez, CHU de Lille, Lille, France*

The advent of laparoscopic adrenalectomy provides the opportunity to assess the advantages and drawbacks of existing surgical approaches. This study reviewed intraoperative and postoperative complications of patients undergoing adrenalectomy via the posterior approach.

Between 1970 and 1992, over 300 adrenalectomies were performed, including 104 via the posterior approach (none of 111 phaeochromocytomas, 38 of 52 Cushing's, 47 of 83 Conn's, four of 20 virilizing or feminizing tumours, 15 of 64 adrenalomas). All tumours were <5 cm in diameter and five were malignant. Adrenalectomy was bilateral in 21 patients (20 Cushing's disease, one Conn's).

The posterior approach was carried out initially in the prone position but currently is performed in the lateral position. A hockey-stick incision was made on the resected 11th or 12th rib.

There was no intraoperative death. During operation, one minimal caval tear and 14 pleural tears occurred and were sutured with pleural drainage in two patients only. One patient died from sepsis after operation. No patient required blood transfusion and none received anticoagulation therapy. All except eight were ambulant the day after surgery. The mean postoperative stay was 4 (range 1–10) days, and after day 4 was justified for non-surgical reasons; it has currently dropped to 2 days.

Adrenalectomy via the posterior approach is safe, comfortable for the patient and allows early postoperative discharge.

Glucose-6-phosphate dehydrogenase activity: a metabolic index in the diagnosis of thyroid carcinoma

P.M. Mercer, D. Murphy, M. Stokes, H.A. Long, D.J. Conway, K. Sheahan, N.J. O'Higgins and P.P.A. Smyth, *Endocrine Laboratory, Departments of Medicine and Surgery, University College Dublin and St Vincent's Hospital, Dublin, Ireland*

Glucose-6-phosphate dehydrogenase (G6PD) activity in epithelial cells within frozen tissue sections can be measured by quantitative cytochemistry based on the transfer of hydrogen ions (H^+) from substrate G6P to a neotetrazolium H^+ acceptor. This reaction is routinely performed in an atmosphere of nitrogen to prevent H^+ reacting preferentially with oxygen to produce water.

G6PD activity is minimal when benign tissues are reacted in an atmosphere of oxygen but in many malignant tissues a significant amount of G6PD activity is retained in oxygen.

In this study G6PD activity was measured cytochemically in thyroid follicular cells, using frozen sections obtained from 16 consecutive thyroidectomies. Sequential sections cut from thyroid tissue were used for measurement of G6PD activity over varying times in atmospheres of nitrogen and oxygen. Mean(s.d.) maximum G6PD activity was significantly greater (62–89 units) in thyroid carcinomatous than in benign tissues (50·0(3·3) units). A significant decline in G6PD activity compared with that measured in nitrogen was observed when sections from benign tissues were measured in oxygen. In the patients with toxic adenomas and in nine of ten with multinodular goitre, G6PD activity in oxygen declined by 66·2–89·1 per cent (average fall to 76·2 per cent of that observed in nitrogen). In contrast to the findings in benign tissues, G6PD activity in oxygen was unchanged or marginally decreased in the three patients with thyroid carcinoma (one follicular, one papillary, one lymphoma).

The results offer the potential of providing a new metabolic test to complement existing histological or cytological diagnoses of thyroid carcinoma.

Papillary thyroid cancer: retrospective analysis of 760 patients treated in a 20-year period

P. Miccoli, A. Pinchera, F. Cetani, S. Giardina, C. Ceccarelli, F. Lippi, E. Martino, C. Spinelli, F. Pacini and J. Lynn, *Istituto di Clinica Chirurgica, Università di Pisa, Ospedale S. Chiara, Pisa, Italy*

The clinical and epidemiological features of 760 patients with papillary thyroid cancer (PTC) (68·9 per cent of all thyroid cancers) treated and followed from 1969 to 1990 were analysed. The outcome was correlated with prognostic factors.

The female:male ratio was 3:1. The mean age at diagnosis was 44 (range 6–85) years with a peak in the fourth and fifth decades; mean follow-up was 5·8 (range 2–21) years.

The presenting symptom was a thyroid nodule in 63·2 per cent of cases; the interval between initial symptoms and diagnosis ranged from 1 to 120 months (<6 months in the majority). PTC was associated with benign thyroid disease, usually non-toxic nodular goitre, in 10·1 per cent of patients and was familial in 2·6 per cent. External radiation in the neck region had occurred in 39 patients (5·1 per cent). Tumour size was <1 cm in 115 patients, 1–2 cm in 137, 2–4 cm in 148, >4 cm in 45 and undetermined in 315.

Surgery was near-total thyroidectomy in 714 patients (93·9 per cent) and subtotal thyroidectomy in 35 (4·6 per cent). According to macroscopic and microscopic pathology, patients were assigned to four groups: class I, intrathyroid disease (401 patients; 52·8 per cent), class II, lymph node metastases (243 patients; 32·0 per cent); class III, extrathyroid extension (107 patients; 14·1 per cent); and class IV, distant metastases (nine patients; 1·2 per cent).

Postoperative treatment included ^{131}I therapy for ablation of thyroid residues and for treatment of functioning metastases, and L-thyroxine suppressive therapy.

Surgical treatment of metastases was limited to a few patients with non-functioning metastases; 40 patients died, 30 from disease and ten as a result of other causes. Tumour-related deaths were significantly correlated with classes III and IV (10·2 and 44 per cent respectively) but not with lymph node metastases.

In this series, significant risk factors were age over 40 years, tumour size >4 cm, extrathyroid extension and/or distant metastases, and subtotal thyroidectomy. Patients with PTC treated with radical surgical and radioiodine treatment enjoy a good prognosis.

Review of current practice in surgical management of benign thyroid disease

B.J. Harrison and M.H. Wheeler*, *Departments of Surgery, Northern General Hospital, Sheffield and *University Hospital of Wales, Cardiff, UK*

Questionnaires were sent to 95 members of the British Association of Endocrine Surgeons to determine whether there is a uniform approach to the management of patients with solitary thyroid nodule or Graves' disease.

Completed questionnaires were received from 37 surgeons (73 per cent teaching hospital based). Of their clinical workload, 3–100 (median 20) per cent was devoted to endocrine surgery. Fine-needle aspiration of solitary thyroid nodules was performed routinely by 73 per cent of respondents. Of these, 78 per cent described this investigation as significantly altering the number of patients selected for surgical treatment. Total lobectomy and isthmectomy was the operation of choice for 68 per cent of surgeons; 10 per cent did not routinely visualize the recurrent laryngeal nerve. Relapse of thyrotoxicosis after one course of antithyroid drugs was felt to be an indication for surgery by 83 per cent of respondents. There was no consensus as to a lower age limit for radioiodine administration. Of the surgeons, 41 per cent would allow an experienced trainee (registrar in 40 per cent of cases) to perform thyroidectomy in their absence.

There was considerable variation in the surgical management of patients with benign thyroid disease, even among those with a declared special interest in endocrine surgery.

Management of thyrotoxicosis during non-thyroid surgery

M. Hartog, L. Gibberd, K. Chen, J. Clark and A.J. Webb, *Departments of Medicine and Surgery, Southmead Hospital, Bristol, UK*

Thyroid crisis is now rarely seen and its treatment is well documented[1]. The management of patients with thyrotoxicosis who require emergency surgery for an intercurrent illness is poorly defined.

Two patients with undiagnosed thyrotoxicosis are presented who required urgent non-thyroid surgery. One patient had a fractured neck of the femur and the other a large bowel obstruction caused by carcinoma of the sigmoid colon. Both patients were rapidly rendered euthyroid with propyl thiouracil[2], iodide and propranolol. Surgery was possible by the start of the second week of admission. Apart from transient sinus tachycardia in one patient, no other complication ensued. The above medical combination is recommended for the rapid control of thyrotoxicosis in patients requiring urgent surgery.

SURGERY ABSTRACTS

Br. J. Surg. 1993, Vol. 80, September, 1210-1211

A selection from the August issue of the American journal.

Use of gene therapy to induce human-mouse xenogeneic chimerism

Ira J. Fox, MD, Eleni Athan, PhD, Jon Fisher, AB, B. Timothy Baxter, MD, Silvio Podda, MD, *and* **Christine Richardson, MA,** *Omaha, Neb., and New York, N.Y.*

Background. *Bone marrow transplantation (BMT) has been used in the laboratory to overcome the immunologic barriers to xenotransplantation and results in chimerism and specific tolerance to donor antigens in lethally irradiated mice. Clinically, BMT carries the considerable risks of graft-versus-host disease and graft failure. Retrovirus-mediated gene transfer could provide a means of introducing foreign major histocompatibility (MHC) genes into host bone marrow cells (BMC) and thus accomplish the immunologic goals of BMT, without the associated risks.*

Methods. *Using a Moloney virus–based vector, a replication defective retrovirus was constructed that contained a complementary DNA encoding the human MHC antigen HLA-A2. Three million C57BL/6 mouse BMC were cocultured for 48 hours with 1 × 10^6 HLA-A2 virus "producer" cells in the presence of 15% WEHI supernatant (interleukin-3) and 200 units/ml interleukin-6. Putatively infected BMC were then used at 2 to 3 × 10^6 BMC/animal to reconstitute lethally irradiated syngeneic mice.*

Results. *Twelve days after reconstitution, spleen colonies were found to have integrated the full-length retroviral sequences. Thirty days after BMT, the introduced DNA could be found in the bone marrow, thymus, and spleen, and approximately 5% of T cells in the spleen expressed the HLA-A2 surface antigen.*

Conclusions. *These data show that xenogeneic MHC genes can be introduced and expressed in mouse hematopoietic cells in vivo and indicate that gene therapy potentially may be used in the future to manipulate the immune system to induce transplantation tolerance. (SURGERY 1993;114:174-82.)*

Composite kidney-islet transplantation prevents recurrent autoimmune beta-cell destruction

Stephen T. Bartlett, MD, Gregg A. Hadley, PhD, Bernadette Dirden, BA, Eugene J. Schweitzer, MD, Sorenna Eans, MD, David Pham, BA, *and* **Cedric Sheffield, MD,** *Baltimore, Md.*

Backgound. *Clinically successful islet transplantation has been rare despite adequate isolation techniques. Reenactment of the original autoimmune β-cell destruction may contribute to the poor results. Distinguishing autoimmune effects from rejection can be accomplished with isogeneic transplants exchanged between diabetes-prone (BB-DP) and diabetes-resistant (BB-DR) rats. These experiments determine the relative sensitivity of islet, whole pancreas, and composite kidney-islet transplants to recurrent autoimmunity.*

Methods. *Acutely diabetic (BB-Ac) BB rats served as recipients of vascularized pancreas, intraportal (IPo) or renal capsular (KC) islet transplants, or vascularized composite kidney-islet grafts from BB-DR or BB-DP donors. Graft function was assessed by daily blood glucose level, and the outcome was confirmed on histologic examination. Cyclosporine 5 mg/kg/day intramuscularly was administered to assess its effect on recurrent β-cell injury.*

Results. *BB-DP pancreases developed recurrent autoimmunity in 55% of cases; cyclosporine afforded complete protection if maintained. Diabetes resistance was transplanted with 23 of 23 BB-DR pancreas grafts; however, islet isolation led to a loss of diabetes resistance for islet grafts to the KC and IPo. Cyclosporine protected KC but not IPo islets. Composite BB-DR kidney-islet transplants functioned indefinitely in all cases.*

Conclusions. *Transplanted islets initally survive by passive diffusion but are ultimately revascularized by capillary ingrowth. The finding that composite kidney-islet transplants function indefinitely suggests that the revascularizing endothelium may play a role in resistance or susceptibility to autoimmune β-cell destruction. (SURGERY 1993;114: 211-17.)*

Extracorporeal life support for adult cardiorespiratory failure

Harry Anderson, III, MD, Cynthia Steimle, MD, Michael Shapiro, MD, Ralph Delius, MD, Robin Chapman, RN, Ronald Hirschl, MD, *and* **Robert Bartlett, MD,** *Ann Arbor, Mich.*

Background. *Extracorporeal membrane oxygenation is routinely used for neonatal respiratory failure but is considered unsuccessful in adults based on old studies and old methods. We conducted a new phase 1 trial of modern extracorporeal life support (ECLS) in moribund adults with cardiorespiratory failure.*

Methods. *Criteria for initiation of ECLS were 90% mortality risk despite maximal conventional care, good potential for recovery, age < 60 years, and no contraindication to anticoagulation. Vascular access for ECLS was performed by operative or percutaneous cannulation. Continuous systemic heparinization was used, maintaining whole blood activated clotting time between 160 to 180 seconds. Blood components were transfused as necessary. Lung management included low rate and low pressure ventilation with an inspired oxygen fraction 0.5 or less.*

Results. *Forty patients were treated with ECLS, 30 with primary respiratory failure and 10 with primary cardiac failure. Twenty-two patients recovered lung or heart function, and 18 patients survived and were discharged from the hospital (14 with respiratory failure and four with cardiac failure, overall survival 45%). The major complication of ECLS was bleeding.*

Conclusions. *With modern techniques, ECLS can be life-saving in adult cardiorespiratory failure when conventional therapy has failed. (SURGERY 1993;114:161-73.)*

Soluble factors modulate changes in collagen gene expression in abdominal aortic aneurysms

D. J. Minion, MD, Y. Wang, MD, T. G. Lynch, MD, I. J. Fox, MD, G. D. Prorok, MS, *and* **B. T. Baxter, MD,** *Omaha, Neb.*

Background. *Although increased procollagen gene expression and synthesis have been implicated in the progression of abdominal aortic aneurysms (AAA), factors modulating this change have not been identified. Furthermore, it is not known whether the increase in AAA procollagen expression is specific to this disease or also occurs in tissue affected by atherosclerotic occlusive disease (AOD). If paracrine rather than autocrine factors are responsible for increased gene expression in AAA, this effect should be transferable to target smooth muscle cells through conditioned media. Our objectives were to determine 1α(I) procollagen messenger RNA levels in AOD tissue compared with normal and AAA and to determine whether differences noted in tissue procollagen gene expression could be transferred through conditioned media from normal, AOD, and AAA tissues to target smooth muscle cells in primary culture.*
Methods. *Normal, AOD, and AAA tissue was used for tissue RNA extraction or was minced and washed with serum-free media (4°C) × 30 minutes and the media applied to human aortic smooth muscle cells (SMC) in primary culture for 36 hours. Total RNA from tissue and SMC exposed to conditioned media was analyzed by Northern and dot blot analysis for 1α(I) procollagen.*
Results. *Relative tissue 1α(I) procollagen levels were not increased in AOD (0.23 ± 0.05) as compared with normal (0.17 ± 0.03); both were decreased compared with AAA (0.53 ± 0.07; $p < 0.01$). The 1α(I) procollagen levels in SMC exposed to conditioned media from AAA (1.73 ± 0.15) were increased ($p < 0.05$) compared with AOD (1.10 ± 0.12) and normal (1.16 ± 0.16).*
Conclusions. *There is no increase in tissue AOD procollagen gene expression. The ability to transfer the same relative patterns of gene expression from tissue to target SMC with conditioned media suggests that paracrine, rather than autocrine, factors modulate procollagen expression in AAA tissues. (SURGERY 1993;114:252-7.)*

Regression of intimal hyperplasia with restoration of endothelium-dependent relaxing factor–mediated relaxation in experimental vein grafts

Mark G. Davies, MD, FRCSI, Michael L. Klyachkin, MD, Helge Dalen, PhD, Einar Svendsen, MD, PhD, *and* **Per-Otto Hagen, PhD,** *Durham, N.C., and Bergen, Norway*

Background. *The reversibility of the morphologic and functional alterations that occur in veins transplanted into the arterial circulation was examined in this study.*
Methods. *Common carotid vein bypass grafts (VG) were performed in 20 male New Zealand White rabbits. Ten VG and jugular veins (CV) were harvested after 14 days, and ten VG were reimplanted as venovenous bypass grafts (REV) and harvested after an additional 14 days. Vessels were taken for structural or isometric tension studies to norepinephrine, serotonin, and bradykinin and to acetylcholine and sodium nitroprusside after precontraction.*
Results. *There was a decrease in the thickness of the intima ($p = 0.02$) and the media ($p = 0.002$) in REV compared with VG. In REV, sensitivity to norepinephrine decreased ($p = 0.0007$) with a reduced maximal tension to norepinephrine ($p = 0.02$) and to serotonin ($p = 0.0001$). Bradykinin sensitivity increased in REV ($p = 0.003$ vs VG) and was greater than in CV. Only the precontracted CV and REV relaxed to acetylcholine. All tissues relaxed to sodium nitroprusside.*
Conclusions. *This study suggests that intimal hyperplasia can be reversed with restoration of endothelium-dependent relaxing factor–mediated relaxation but that only a partial regression of the contractile abnormalities can be achieved. (SURGERY 1993;114:258-71.)*

Intercellular communication and maintenance of islet cell mass—Implications for islet transplantation

P. Metrakos, MD, S. Yuan, MD, D. Agapitos, BSc, *and* **L. Rosenberg, MD, PhD,** *Montreal, Canada*

Background. *The major emphasis in islet transplantation has been the development of methods to enhance islet purity. This focus assumes that islets do not require support from other cellular elements of the pancreas. We chose to examine a possible duct-islet interaction because of the embryologic origin of islets from ductal epithelium.*
Methods. *Duct and islet cells were prepared by collagenization of hamster pancreas and purified on a bovine serum albumin gradient. Primary duct cultures were passaged twice. Duct-conditioned medium was collected from the tertiary cultures. Three groups of cultures were established: group 1, 100 islets/plate in minimal medium (Dulbecco's modified Eagle medium/F12); group 2, 100 islets + 40 duct fragments/plate in Dulbecco's modified Eagle medium/F12; and group 3, 100 islets/plate + duct-conditioned medium. After a 3-day incubation, tritiated thymidine (1 µCi/ml) was added for 24 hours. The islets were separated from the ducts by handpicking and then sonicated. DNA was measured (µg) fluorometrically and tritiated thymidine incorporation, a measure of cell proliferation, was determined in trichloroacetic acid-precipitated material by liquid scintillation. Data (mean ± SEM) were compared by two-tailed Student's t test.*
Results. *Tritiated thymidine incorporation into islet cells in minimal medium (81.1 ± 24.6 disintegrations per minute [dpm]/µg DNA [$n = 8$ plates]) was less than 25% ($p < 0.001$) of that of islet cells cocultured with ducts (323.2 ± 54.5 dpm/µg DNA [$n = 6$]) or with duct-conditioned medium (389.7 ± 27.6 dpm/µg DNA [$n = 5$]).*
Conclusions. *Pancreatic duct epithelium can stimulate islet cell proliferation in a paracrine manner. (SURGERY 1993;114:423-8.)*

Laparoscopic repair of perforated peptic ulcer

Sir

The surgical literature is currently flooded by numerous reports describing additional applications for non-invasive laparoscopic technology. Such is the observation of Messrs Walsh, Khoo and Motson (*Br J Surg* 1993; **80**: 127), who offer a novel approach to the laparoscopic treatment of perforated peptic ulcer. The authors perform laparoscopy to confirm or refute the diagnosis of perforation. If confirmed, the presence or absence of a naturally occurring omental patch is noted. If this is absent they convert to an open omentopexy procedure. If there is a naturally occurring omental plug, it is left alone and peritoneal lavage performed through one of the cannulas.

The authors correctly state that they 'see no merit in disturbing an omental patch already in place merely to spend a long time putting it back'. The existence of that naturally occurring omental plug and the notion that it should not be disturbed was described by Taylor and Warren[1] many years ago and applied in the conservative treatment of perforated ulcers. Accurate diagnosis of perforation does not require laparoscopic 'confirmation or refutation'. When spontaneous sealing of the perforation has occurred, as verified by a contrast study[2], most perforations are successfully treated without operation, i.e. without laparotomy, laparoscopic diagnosis or any form of peritoneal toilet[3,4].

Sutureless laparoscopic treatment of perforated duodenal ulcer

Sir

Laparoscopic treatment of perforated peptic ulcer was first reported in 1989. Various techniques have since been described. Mr Tate and colleagues (*Br J Surg* 1993; **80**: 235) recently reported the technique of omental patching using fibrin glue, but no results were presented. We report the outcome in ten patients with perforated duodenal ulcer who underwent laparoscopic repair using fibrin glue.

Eight men and two women of mean age 46 (range 23–91) years have been treated in the past year. In three cases there was a history of duodenal ulcer. All patients were correctly diagnosed before operation. The median delay between perforation and treatment was 8 (range 2–22) h. Eight patients underwent immediate operation and two had attempted conservative management by nasogastric aspiration for 8 and 24 h.

At laparoscopy the perforation was confirmed as on the anterior surface of the duodenal bulb in all cases. After separation of fibrous adhesions and copious peritoneal lavage (mean 7 litres), the perforation was closed by application of omentum using fibrin glue. A suction drain was placed in the subhepatic region. Postoperative management included nasogastric aspiration for 3 days, with intravenous fluids, antibiotics and antisecretory agents.

The mean duration of the operation was 97 (range 70–130) min. Ileus resolved after a median of 44 (range 18–72) h, with normal feeding resumed by day 6. The mean hospital stay was 8 (range 6–11) days, and there was no associated morbidity or mortality. All patients remain asymptomatic at 3 months. Seven patients have had follow-up endoscopy, which showed incomplete healing in one case only.

Laparoscopic treatment of perforated peptic ulcer is of considerable interest[1,2]. Although peritoneal lavage may be achieved without difficulty, endoscopic suture of the perforation is technically demanding. An alternative technique, with traction of the omentum through the perforation, has been suggested[3] but remains unproven. In contrast, application of omentum with fibrin glue is a simple, quick and safe procedure that has given good results in our experience.

Emergency laparoscopic surgery

Sir

We were interested to read Mr Paterson-Brown's Review on emergency laparoscopic surgery (*Br J Surg* 1993; **80**: 279–83), particularly in reference to the management of acute appendicitis. This condition has been referred to as 'the great leveller' as diagnostic accuracy has always been poor compared with other conditions, whatever the grade of surgeon. Methods of improving the negative appendicectomy rate include laparoscopy, ultrasonography and computer-aided diagnosis, but these are not widely used.

We recently audited appendicectomy in our own hospital for the year 1991–1992. A total of 126 patients underwent appendicectomy, of whom 34 (27 per cent) had histologically normal appendices. Of these, 19 were male and 15 female. The range of alternative findings was very similar to that in Paterson-Brown's article, and we had 21 patients (13 male, eight female) in whom no pathological reason for symptoms could be identified.

Although Paterson-Brown recommends laparoscopy for *women* before laparotomy for presumed appendicitis, our results suggest that men are just as likely to undergo negative appendicectomy as women and should therefore not be excluded from laparoscopy. It has also been shown that the negative appendicectomy rate is equal in patients in whom the diagnosis of acute appendicitis is 'certain' or 'uncertain'. Perhaps laparoscopy should be performed on all patients before appendicectomy, therefore.

Most appendicectomies are performed by surgical trainees. As laparoscopy becomes more accepted in general surgery, it should become an integral part of basic surgical training. At present it is generally accepted that, if a patient has an incision in the right iliac fossa, they have undergone appendicectomy. As more appendicectomies are being performed laparoscopically, we may require other means of telling whether or not the appendix is still present.

Laparoscopic resection of a bleeding gastric tumour

Sir

I read with interest the Surgical Workshop by Mr Abercrombie and colleagues (*Br J Surg* 1993; **80**: 373) but would take issue with the ultimate sentence, which implies that there are no risks with laparoscopic resection. This was a surgical procedure requiring 3 h of general anaesthesia with potential morbidity and mortality.

Open resection of small gastric tumours with assessment of the liver and regional nodes is safe in experienced hands. I doubt whether there are data comparing open and laparoscopic approaches to this problem, and until such time as these become available the conclusion drawn is invalid on the basis of a single case.

Photoplethysmography in the diagnosis of superficial venous valvular incompetence

Letter 1

Sir

The paper by Dr Rutgers and colleagues (*Br J Surg* 1993; **80**: 351–3) concludes that 'photoplethysmography is not the non-invasive method of choice in the routine evaluation of superficial venous valvular incompetence'. This statement may be true for a routine examination used in a group that includes the many varicosities (even large ones) that do not allow sufficient downflow to affect refilling time; it does, however, under-rate the capabilities of photoplethysmography when there is clinical evidence of venous hypertension, such as pigmentation or ulceration. Here, substantial shortening of the refilling time recorded by photoplethysmography is always found. Essentially, photoplethysmography cannot recognize a lesser degree of superficial venous incompetence but can reliably demonstrate when a venous pumping mechanism is proving inadequate, which may be caused by overwhelming superficial incompetence or by defective deep veins. It is here, in the presence of obvious abnormality, that photoplethysmography comes into its own and is able to give positive identification of superficial incompetence as the cause.

In using photoplethysmography for this purpose, preliminary clinical examination should always include a careful mapping out of enlarged superficial veins both visually and by the tapwave technique. Directional Doppler flowmetry is then applied to any suspected pathway of incompetence and in most cases will show the characteristic downflow of simple incompetence after squeezing or exercise; this may be sufficient evidence to decide on treatment. If there is a history suggesting previous deep vein thrombosis or if venotensive skin changes are present, especially ulceration, then photoplethysmography should also be carried out and repeated with fingertip compression to appropriate superficial veins. The use of a venous tourniquet or cuff is a prime source of error, which may cause artefact through venous congestion or be insufficient to prevent gravitational downflow in the superficial veins. Far better is to use localized fingertip pressure over the suspected pathway of superficial incompetence to see whether this causes the recording to revert to normal. Both the presence of such a pathway and its position are thereby confirmed; only clearly repeatable results should be heeded. Superficial incompetence is demonstrated beyond doubt by return of refilling time to normal but, by contrast, deep vein problems will never give this response. If Doppler flowmetry has shown upflow in superficial veins, accentuated by exercise, and the photoplethysmography recording cannot be made to revert to normal by any manipulation to superficial veins, then post-thrombotic syndrome or other deep vein problem is probably present. It is then essential to clarify the cause by functional phlebography or ultrasonographic imaging.

Photoplethysmography should not be discarded too readily. Once its limitations are realized, its use confined to patients with clinical evidence of venous hypertension, and a venous tourniquet or cuff abandoned in favour of localized fingertip pressure, photoplethysmography provides a rapid simple method of distinguishing between surgically treatable superficial incompetence causing venotensive changes and a deep vein state where operation has little place. Air plethysmography is of course a superior alternative, capable of giving quantitative measurement of venous blood expelled by exercise. However, this is more time-consuming and perhaps best reserved for use when results of photoplethysmography are inconclusive.

Photoplethysmography and variants of it remain an excellent initial screening test in the circumstances outlined. The need for brevity in this letter prevents elaboration, but more details have been given elsewhere[1].

Letter 2

Sir

We read with interest the article by Dr Rutgers and colleagues (*Br J Surg* 1993; **80**: 351–3) comparing photoplethysmography and clinical investigation combined with Doppler ultrasonography in the diagnosis of superficial venous incompetence. They point out that photoplethysmography is not the non-invasive method of choice for routine evaluation. We think that the methods and conclusions need some comment.

First, the number of non-interpretable results of photoplethysmography is strikingly high. Conditions for correct measurement are that the patient should be older than 20 years, the skin temperature higher than 28°C, and it is necessary that the ankle joint has full mobility[1]. Furthermore, it has been recommended that three measurements should be taken to improve the accuracy[2]. In the case of a non-interpretable result one should repeat the measurement.

Second, it has never been claimed that photoplethysmography detects reflux. Thus Rutgers *et al.* compare a method detecting reflux and one that is closely correlated with the venous refilling time. The value of photoplethysmography is shown by the fact that the venous refilling time correlates well with the venous refilling time as measured by the direct invasive phlebodynamometric method (ambulatory venous pressure measurement); this has been shown in several studies[3,4]. This technique is still the ideal standard for the evaluation of venous disease[5]. It allows evaluation of the muscle pump function as well as the resting venous pressure and the refilling time. There is still no comparable non-invasive technique.

Third, it has never been claimed that photoplethysmography alone is optimal for screening of varicose veins. It should always be used in combination with, for example, Doppler ultrasonography. Although the methods overlap, they are clearly complementary[6].

Finally, incompetence of the long saphenous vein can be partial. If only the proximal part is incompetent, this will not influence the refilling time as measured by photoplethysmography near the medial malleolus. The extent of incompetence of the saphenous vein should therefore be described[7].

Light-reflection rheography is a new technique based on the principle of photoplethysmography. Digital photoplethysmography is a further development of light-reflection rheography and is currently the best test available[8]. The instrument adjusts the emitted light until a predetermined signal level of the reflected light is obtained, thus compensating for the different conditions of cutaneous optical density.

In conclusion, photoplethysmography, light-reflection rheography and digital photoplethysmography are inexpensive non-invasive methods to be used in routine phlebological practice. In combination with Doppler ultrasonography they provide a reliable pretreatment screening test for varicose veins.

Letter 3

Sir

In the paper by Dr Rutgers and co-workers (*Br J Surg* 1993; **80**: 351–3) it is suggested that photoplethysmography is not the non-invasive method of choice for routine evaluation of superficial venous valvular incompetence of the leg. This conclusion is based, in part, on a 22·1 per cent rate of uninterpretable traces and in part on a poor correlation with ultrasonographic findings. Three factors seem likely to account for the conclusion: the definition of an 'uninterpretable trace', the use of a 50 per cent refilling time to solve their problems and the reliance on a single tourniquet. The original definition of an endpoint[1] was the point at which the horizontal baseline was reached for 5 s. Uninterpretable traces were extremely rare in our experience of over 200 studies per month over 12 years, using the Medasonics Photopulse Plethysmograph with the Medasonics PH-77 Phototransducer and using first a low-thigh tourniquet and then a calf tourniquet.

Since the initial report[1] in 1979 and with the progressive sophistication of ultrasonographic equipment, it is our experience that duplex scanning is highly accurate for the quantification and localization of reflux through specific incompetent valve areas. However, unlike photoplethysmography, duplex scanning does not reflect the overall sum of the effects of reflux on the gaiter area – an area of major morbidity. Indeed, single or multiple valvular incompetence can exist without the reflux necessarily being transmitted to the gaiter area. Proper treatment of venous insufficiency includes the treatment of varicose veins themselves and the dermatological changes resulting from this incompetence. Adequate assessment of venous insufficiency requires both the overall quantification of the defect and the determination of the source of venous reflux. Venous reflux photoplethysmography has an advantage over duplex scanning since it permits assessment of the extent to which the abnormal venous reflux is transmitted to the cutaneous tissue in the particularly sensitive gaiter area. Abnormal photoplethysmographic findings related to this area may predict the anticipated morbidity and guide early preventive measures.

While it is true, as emphasized by Van Bemmelen *et al.*[2], that the diagnosis of superficial venous insufficiency by duplex scanning is often 'missed' by photoplethysmography, this ostensibly negative finding is in fact of great prognostic value. A negative photoplethysmography result in the presence of a positive duplex scan probably indicates that, despite evidence of localized insufficiency (superficial or deep), this reflux is not transmitted to the skin of the gaiter area, and the likelihood of severe dermatological changes may be minimal. Thus, venous reflux photoplethysmography remains a valuable, simple, inexpensive and non-invasive tool to assess not only the abnormal venous physiology affecting the gaiter area, but also its source and relative severity. After operation, photoplethysmography permits both short- and long-term follow-up of the degree to which the surgical intervention corrected the reflux transmitted to the gaiter area.

Anaemia and surgery

Sir

The concern about blood transfusion and surgery[1–3] is exemplified by the Leading Article on autotransfusion and salvaged blood by Messrs Chant and Thompson (*Br J Surg* 1992; **79**: 389–90). Working in a tropical country and being much affected by the shortage and costs of safe blood, we tried to determine more closely the situation in which perioperative blood transfusion is essential. We prospectively examined 3 years (1989–1991) of major operations, both emergency and elective.

The study population was a series of 212 patients who underwent operation but were not transfused during the hospital stay. The preoperative and postoperative haemoglobin levels were recorded plus the amount of blood lost during the operation, the duration of admission (after operation) and the final outcome. The need for blood transfusion was assessed, together with the risk attributable to anaemia during anaesthesia and surgery. Patients were divided into two groups according to the preoperative haemoglobin level, using the traditional threshold of 10 g/dl; there were 106 patients in each group. The test group was defined as patients with a preoperative haemoglobin level < 10 g/dl (mean 7·9 g/dl). Their mean postoperative level was 6·7 g/dl, mean blood loss 650 ml and median admission period 7·7 days. The controls had a preoperative haemoglobin level above 10 g/dl (mean 12·1 g/dl). Their postoperative haemoglobin level was 11·0 g/dl, mean blood loss 495 ml and median admission period 7·3 days. The diagnoses, anaesthetics and surgical operations were similar in the two groups; intraoperative and postoperative management was otherwise identical and the blood volume was maintained with standard methods.

The relation between anaemia (preoperative haemoglobin level and blood loss) and death was as follows. Eight patients died overall (3·8 per cent), but the mortality rate was not related to the preoperative haemoglobin level: three patients died in the test group and five among the controls (P = 0·41). Likewise, postoperative hospital stay was the same (7·7 *versus* 7·3 days, P = 0·79).

The results question current beliefs regarding an acceptable haemoglobin level and the need to transfuse anaemic patients before or after operation; the traditional threshold of 10 g/dl should be re-examined. This study did not examine the precise level below which transfusion decreases mortality rate and above which it is useless or even dangerous (bearing in mind the need to avoid transfusion-associated human immunodeficiency virus and hepatitis transmission). The data do suggest that there is no evidence of increased risk up to a haemoglobin level of 8 g/dl and that the preoperative haemoglobin level alone cannot be a sufficient index for assessing the risk related to anaemia.

Porcine islet isolation: prospective comparison of automated and manual methods of pancreatic collagenase digestion

Sir

We congratulate Mr Toomey and colleagues for conducting a prospective comparison of automated and manual methods of isolating porcine islets of Langerhans (*Br J Surg* 1993; **80**: 240–3). Although comparative analysis of islet isolation techniques is welcome, manual methods of porcine islet isolation should not be dismissed on the basis of their report.

We have developed a simple inexpensive method of porcine islet isolation[1], in which collagenase solution is injected directly into the pancreas at multiple sites. The gland is cut into small pieces and digested in collagenase solution at 37°C with gentle agitation. No attempt is made to assess accurately the rate of tissue dissociation, and the trauma of tearing apart the digested pancreas is avoided. Intraductal injection of collagenase confers no benefit over direct injection into the pancreas using this isolation process[2].

Table 1 compares islet yields from the pancreas of young Large White–Welsh crossbred pigs using our manual method with those reported by Toomey *et al.*

Table 1 *Comparison of methods of islet purification*

	Leicester		Worcester
	Automated	Manual	Manual
Weight of pigs (kg)	80–100	80–100	15–40
No. of experiments	7	7	6
No. of islets per g pancreas*	4014 (2733–6920)	2698 (2013–5591)	31 380 (14 622–72 400)
Total islet tissue volume (mm^3 per g pancreas)*	3·56 (1·39–5·30)	1·07 (0·46–1·92)	6·03 (2·77–13·30)
105-μm islet equivalents per g pancreas*	5875 (2294–8746)	1766 (759–3168)	9952 (4571–21 975)
Islet equivalent:islet ratio	1:0·7	1:1·5	1:3·2

*Values are median (range)

Islets obtained from these younger pigs were maintained in culture, and they responded to stimulation by insulin secretagogues during perifusion. Although the islet equivalent:islet ratios indicate that smaller and possibly fragmented islets were obtained by our method, the total islet tissue volume exceeded that obtained using the automated process. However, the influence of donor age on the efficacy of islet isolation methods is recognized.

For the purpose of comparison, we have expressed our islet yields on the basis of 105 μm. However, we were surprised that the authors deviated from the internationally agreed islet equivalent diameter (150 μm) used to assess and compare islet yields in large mammals and humans. The presentation of data on this basis may foster confusion and hinder comparison of their results with previously published findings on porcine islet isolation from other centres.

Authors' reply

Sir

We are grateful for the interest that Mr Downing and colleagues have shown. Yields of porcine islets depend crucially on the strain and age of pig and, even more importantly, on the batch of collagenase used. Indeed, the batch of collagenase used may influence the yield of islets by up to tenfold. Because these factors vary so much from one laboratory to another, it is not possible to make comparisons between laboratories and we cannot therefore comment on the yields of islets achieved with the strain of pig and batch of collagenase used in Worcester. Our study was designed such that the only variable was whether digestion was automated or manual; the automated method came out on top.

We explained in the paper why we used a 105-μm equivalent islet. If one intends to look at the efficiency of islet isolation by comparing the ratio of islet equivalents to absolute islet counts, then this ratio is relevant only if one uses an islet equivalent diameter derived from the islets within the donor pancreas. We feel that this approach is scientifically correct and should not foster confusion or hinder comparison with results from other centres because, sadly, it is not possible to make meaningful comparison between groups because of the variables discussed.

Abdominal aortic aneurysm: still missing the message

Sir

The paper by Mr Craig and colleagues (*Br J Surg* 1993; **80**: 450–2) provides an excellent report of the large number of patients who present with ruptured or acutely symptomatic abdominal aortic aneurysm that might have been previously diagnosed and electively repaired. We would like to add a further group of patients, not identified by this study, who should be suspected to have aortic aneurysm until proved otherwise.

We have recently reviewed 87 patients who attended this hospital over the past 11 years with embolic disease affecting either the upper or lower limbs. Follow-up of these patients revealed that two died from ruptured aortic aneurysm during convalescence. One patient died in a convalescent hospital 2 weeks after femoral embolectomy. The other was admitted as an emergency 3 months after embolectomy; a ruptured aortic aneurysm was confirmed at laparotomy. Further deaths from ruptured aortic aneurysm may have occurred at home and not been identified.

Patients who present with embolic disease of the lower limb should undergo ultrasonography of the abdominal aorta to exclude aneurysm as the origin of the embolus.

Life quality and psychological morbidity with an ileostomy

Sir

We find it difficult to extract any meaningful message from the study by Mr Awad and co-workers (*Br J Surg* 1993; **80**: 252–4). Perhaps attention to the study design factors reported by Fraser[1] in his excellent review would have improved the quality of data generated.

First, the review is retrospective and without a control group. As such the data provide only a 'snapshot' of opinion in a group that has probably become adapted to life with an ileostomy. More meaningful data would have been obtained if the study had been performed prospectively with analysis before and after operation in a patient cohort with ileostomy or by prospective randomized comparison with restorative proctocolectomy.

Second, the response rate is low (82 of 113) and under one-third of the replies are from patients known to have had ulcerative colitis. Such low compliance rates and population heterogeneity lead to volunteer bias with its inevitable effect on validity.

Third, it would be reassuring to know that the subjects were supplied with information on the ileal pouch procedure such that an unbiased informed opinion could be expressed by the participants on the merits and drawbacks of restorative proctocolectomy.

Although quality-of-life measurement is increasingly important in surgical audit, for these measures to influence clinical practice will require a uniform approach with well validated instruments and standard methodology[1].

1. Fraser SCA. Quality-of-life measurement in surgical practice. *Br J Surg* 1993; **80**: 163–9.

Authors' reply

Sir

Thank you for allowing us the opportunity to comment on the letter from Messrs Kmiot and Bramhall. It is disappointing that they were unable to extract any meaningful message from our study, as we felt that we had made it clear that, in the current climate of opinion regarding restorative proctocolectomy, it is very unlikely that a prospective randomized trial evaluating this procedure against classical panproctocolectomy with ileostomy would now be possible. It follows that an evaluation of the procedure must proceed by other methods, one of which we outlined in our paper. It is surprising that reference is made to the report by Fraser[1] as this paper was published in the same issue of the Journal as our own; short of privileged sight of the manuscript well before publication, we could hardly have taken account of factors mentioned in that study.

Our review was retrospective and without a control group, and the 'snapshot' of opinion referred to was at a mean follow-up of 13 years in a substantial number of patients who naturally had adapted to life with an ileostomy. We contend that the only valid way to assess an operation is at a considerable time after its performance when the trauma associated with the procedure has subsided and when a proper assessment can be made of the quality of life. It is difficult to see, therefore, how more meaningful data would have been obtained if the study had been prospective. Few surgeons in their working life would be able to follow substantial numbers of cases for a long time, and certainly not 44 years, the longest follow-up in our series. Since we do not live in an ideal world, it is therefore unrealistic to expect such studies to be performed prospectively in a randomized fashion for the two operations.

We disagree that the response rate (82 of 113) is low and refer the authors to Bland[2] who states 'the proportion of a sample from whom data is obtained is called the response rate and in a sample survey of the general population is likely to be between 70% and 80%'. The possibility that those lost from our sample may be ill must obviously be taken into account, but we were aware from review of notes available that this was not the case. In a study of mortality among responders and non-responders, Alderson[3], basing his statements of those of Doll and Peto, suggested that the effect of non-response due to ill health at the time of an initial questionnaire had disappeared by the fourth year of follow-up. Our study had a mean follow-up of 13 years. Most of our patients underwent operation for ulcerative colitis; a point brought out in the questionnaire was that few of them seemed to be quite certain of their diagnosis.

The subjects were supplied with information on the ileal pouch procedure, concerning percentage reoperation rate, frequency of bowel motion and complications such as pouchitis. It is impossible to be certain in any questionnaire-based patient survey that bias does not exist, just as it is extremely difficult to obtain unbiased informed opinion from surgeons themselves. The instrument used in our trial to assess psychological morbidity has been well validated and is recognized as the 'gold standard'[4].

Laparoscopic operations in paediatric surgery

Sir

The Leading Article by Mr Miller (*Br J Surg* 1992; **79**: 986–7) makes interesting reading. The author highlighted the current concept of endoscopic surgery and rightly gave prominence to Semm's pioneering work in laparoscopy[1]. However, laparoscopy in paediatric surgery is not quite as novel as the author suggests. Isakov *et al.*[2] published a detailed account of its use in adhesive obstruction in children, and Blinnikov[3] also used it to assess and treat intra-abdominal adhesions. Comparison of conventional and laparoscopic methods in adhesive obstruction showed advantages for laparoscopy in terms of short hospital stay and early return to school[4,5].

Laparoscopy has been used to exclude surgical intervention in a whole range of non-surgical acute abdominal conditions in children who presented with signs and symptoms of acute abdomen[5]. Dronov (unpublished work) combined endoscopic evaluation of the small intestine with pneumatic reduction of intussusception in infants. The additional use of laparoscopic manipulators could assist the reduction while checking for signs of necrosis and possible perforation.

Carcinoid tumours of the appendix in children 1957–1986: incidence, treatment and outcome

Sir

Mrs Parkes and colleagues (*Br J Surg* 1993; **80**: 502–4) report an extensive and interesting study of carcinoid tumours of the appendix in children. However, some of the conclusions based on their data are difficult to accept.

First, consistent histological examination of all appendices in the paediatric age group is recommended. The authors do not state whether residual tumour was identified in the right hemicolectomy specimen of the child with gangrenous appendicitis and a carcinoid tumour. This fact is important since it was the only possible case from more than 40 000 appendicectomies in which histological detection of the tumour may have been advantageous to the patient. Nevertheless, the authors state that their findings 'underline the continuing need for histological examination of all appendices removed from children'. Histopathological examination of appendicectomy specimens in children is important for a variety of well documented reasons[1], but the data presented do not provide a convincing argument based on the detection of carcinoid tumours.

Second, the authors report that appendicectomy alone is confirmed as usually curative, although right hemicolectomy is occasionally necessary. The study provides no support for the latter part of this statement. Appendicectomy alone is adequate treatment for localized tumours $<2{\cdot}0$ cm in largest dimension, but the need for right hemicolectomy for larger appendiceal carcinoids in children is uncertain. In a study spanning six decades at the Mayo Clinic, Moertel *et al.*[2] encountered three patients under 20 years of age with carcinoid tumours of the appendix measuring $\geqslant 2$ cm. In no case was residual or metastatic tumour identified in the subsequent hemicolectomy specimen. None of the tumours reported by Parkes *et al.* was >2 cm in diameter. Histological features such as the depth of tumour invasion are known to be of doubtful prognostic significance in this age group[2].

Third, the importance of long-term follow-up is emphasized. Cases of fatal and metastatic carcinoid tumour of the appendix have been reported in young adults, occasionally after an interval of many years, but either the original tumour in these cases was >2 cm or local metastases were evident at the time of initial operation[2,3]. As in this report, no recurrent disease has been documented in children with appendiceal carcinoid tumours in other large long-term studies[2,3]. Prolonged follow-up is justified in few selected patients.

Authors' reply

Sir

We are grateful to Mr Stringer for his interest in our study, the primary aim of which was to describe carcinoid tumours of the appendix from an epidemiological point of view and in particular to assess their incidence and outcome in children.

We respond specifically to Mr Stringer's three points. First, no residual tumour was detected in the hemicolectomy specimen of the child with the gangrenous appendix; the procedure had been carried out on the recommendation of the pathologist, who was of the view that the tumour had extended beyond the mesoappendix. We suggested routine histopathological examination of paediatric appendices since, as Mr Stringer points out, histopathological examination of these organs is already performed for other reasons and the discovery of a tumour would thus involve no extra work. The detection of large, aggressive or partially resected tumours may merit further assessment of the patient and can only be advantageous.

Second, the statement that right hemicolectomy is occasionally necessary was based on the fact that the procedure had been carried out in two of our patients on expert histopathological advice, together with the recommendation of other authors that it should be considered in tumours >2 cm in size. Since we did not find any tumours of this dimension, we could not comment on the need for further surgery in these patients and chose to accept previously stated opinions on such surgical aspects.

Third, we accept Mr Stringer's point that long-term clinical follow-up of the individual patient is indicated only in the circumstances he describes. For epidemiological purposes, long-term follow-up of patients with these tumours, as with all tumours of children, is available through cancer registration links with the National Health Service Central Register. This system has provided us with much valuable information, which has enabled description of the excellent prognosis in these patients.

We appreciate that opinion remains divided on the best surgical management of these patients, and we were not wishing to prescribe procedure or long-term clinical follow-up.

Laparoscopic herniorrhaphy

Sir

The recent letter by Mr Schraibman on laparoscopic herniorrhaphy (*Br J Surg* 1993; **80**: 538) is interesting but, sadly, very negative. How would surgery ever advance if this were the attitude of all surgeons to new ideas? Of course, for any new procedure to become widely accepted it is necessary that randomized prospective trials be carried out; such a study is already well advanced at St George's Hospital. However, before such trials can be started a reliable technique must be developed to allow worthwhile comparison with conventional alternatives.

Many of the statements in the letter do not stand up to examination. The implication that conventional herniorrhaphy is the 'gold standard' repair with a recurrence rate of only 0·3 per cent and that it is free from complications is simply not consistent with experience in the real world. Indeed, if this were true why have more than 80 different hernia repairs been described? Recurrence rates of up to 20 per cent for primary sutured hernia repair and 30 per cent for recurrent hernia have been reported. Let us not forget that Shouldice had an initial recurrence rate of 17 per cent in 1945 improving to 1 per cent after 5 years[1]. Such figures must surely have been discouraging, but experience luckily continued. Equally 'horrifying' complications occur with open operation and probably more frequently. This seems to have been forgotten in the recent adverse press regarding 'keyhole' surgery. A study of the literature shows a range of complications of conventional hernia repair including ischaemic orchiditis, haematoma, neuralgia, intestinal and urinary fistula, wound infection and, rarely, vascular injury.

We do not accept the comments about a take-up rate of less than 50 per cent by 'informed' patients. On the contrary, despite a full explanation to patients detailing the ongoing experience of the surgeons and the experimental nature of the repair, of over 180 patients offered the procedure since May 1991, only two have refused. Is the method really so experimental? In reality it is merely a new way of doing a well established operation with an excellent record. Evidence from the work of Stoppa, Nyhus, Lichtenstein and others[2] using an open patch technique shows a low recurrence rate; the few that do arise occur mostly in the early postoperative period. This has been the experience of most laparoscopists and, with the refinements in technique and instrumentation that have already taken place, it seems reasonable to predict that recurrence rates will be low. It is interesting that with recurrent hernia even proponents of the Shouldice technique have come to accept that in some cases better results are obtained using a prosthetic mesh[3]. Laparoscopic insertion of such a patch might improve the poor results of open suture techniques for recurrent hernia.

Of course there will be a 'learning curve', but this need not be long and there are already many surgeons experienced in the various techniques, ready and willing to teach in exactly the same apprentice manner as surgery has always been taught. There will be problems, but none should be insoluble. It is the responsibility of surgical teachers to ensure that appropriate tuition is made available to all trainees, and this is essential if we are to maintain the confidence of the public and avoid unnecessary disasters.

We suggest that laparoscopic hernia repair can be performed safely, reliably and cost-effectively, often on a day-case basis. It is likely that hospital costs will remain somewhat higher than for open hernia repair, but not excessively so as the basic equipment is already available. However, costs to the community and society as a whole are much reduced.

Preliminary but mounting evidence suggests that following laparoscopic hernia repair recovery is much quicker, with reduced postoperative pain and the ability to return to normal activities, including heavy work, within a few days of the procedure. However open repair is performed, postoperative discomfort is usually marked and the time off work in this country remains as long as 7 weeks.

Intermittent claudication incites systemic neutrophil activation and increased vascular permeability

Sir

We feel that there are some inconsistencies in the use of data in the above paper (*Br J Surg* 1993; **80**: 181–4), and have some difficulty understanding the experimental methods as described. Under Materials and Methods, the authors state that stimulation at 10 Hz for 10–15 min seven times a day for 14 days was used as a model for claudication. However, during fluorescence microscopy the muscle was stimulated at the rate of 1 Hz for 10 min, which would seem unlikely to be fast enough to precipitate fatigue as demonstrated in the first part of the experiment.

The authors recorded percentage leucocyte adherence in five post-capillary venules in each rat, there being four rats in each group. This they have considered as 20 different observations. In the statistical analysis, the authors have assumed that the resulting 20 observations are independent of each other and may be treated as from a population of 20 subjects. This is not the case, since these were obtained from only four rats, which for statistical purposes should be treated as four subjects. The authors then state that mean percentage adherence was calculated for each group, and that these data were distributed normally, allowing them to use Student's unpaired *t* test and ANOVA (also for normally distributed data) on four numbers instead of non-parametric tests.

In measuring vascular permeability using the urinary bovine serum albumin:creatinine ratio, the authors state in the text that they used the Wilcoxon rank sum test. We are not certain why some of the data were assumed to be normally distributed, while others required non-parametric analysis from the same experimental animals. Yet in *Figure 5* they have given significance values using Student's unpaired *t* test (for 'normally distributed' data). It is unclear whether these data are distributed normally; *Figure 5* suggests the contrary. We suggest that the Mann–Whitney *U* test should have been used for both leucocyte adherence and vascular permeability, as both Student's unpaired *t* test and the paired Wilcoxon rank sum test appear inappropriate.

Authors' reply

Sir

Messrs Andaz and Shields appear to have misunderstood our study. The gentle stimulation was not intended to precipitate muscle fatigue but merely to induce leucocyte adherence and changes in vascular permeability, which it clearly did. A 10-Hz regimen would undoubtedly have produced greater changes, but the results would have been impossible to observe owing to the rapid twitching of the muscle.

We believe that the statistical methods used to analyse leucocyte adherence were appropriate; indeed, the addition of ANOVA was suggested by the Journal's referee. Four rats from each group were sufficient to demonstrate an obvious difference between the ligated-stimulated rats and the others; the killing of more animals would have been unjustified.

Differences between groups in bovine serum albumin:creatinine ratios were analysed by the Wilcoxon test as stated in the text. We apologize that the mistaken reference to Student's *t* test in the legend to *Figure 5* was not recognized at proof stage.

We are disappointed that this comment on our paper adds nothing to the understanding of systemic responses to ischaemia and feel that the results displayed in *Figures 2* and *5* indicate obvious differences between groups without the need for didactic statistical debate.

Statistical comment

Sir

Messrs Andaz and Shields raise two important statistical issues relating to the paper by Mr Hickey and colleagues. The first point relates to the analysis of multiple observations per animal. Unfortunately, neither the original article nor the authors' reply makes it explicit how these data were handled. If, as Messrs Andaz and Shields suspect, the 20 observations per group were analysed as if they were 20 independent observations, then this is a serious statistical flaw[1] that throws considerable doubt on the authors' conclusions. Had the original *Figure 2* shown the actual data points (as was done for *Figure 5*), or had the authors quoted the actual values of the test statistics and the corresponding degrees of freedom (as is recommended in the Journal's statistical guidelines for authors[2]) then this ambiguity would not have arisen, and it would have been straightforward for the reader to assess the appropriateness of the statistical analysis.

The second point relates to the choice of an appropriate statistical test. I suspect that this is more a confusion over nomenclature, which is not helped by a lack of consistency between different statistical texts. The data in *Figure 5* could not possibly have been analysed by a paired procedure such as the (paired) Wilcoxon signed rank test, as the groups are not even of equal size. I can only presume that the authors actually used the unpaired Mann–Whitney *U* test, which is also known as the Wilcoxon–Mann–Whitney test.

Fully implantable venous access systems

Sir

We read with interest the article by Dr Ramirez and colleagues on fully implantable venous access systems in patients with cancer (*Br J Surg* 1993; **80**: 347–8). We fully agree with the authors' view that these devices are safe, reliable and helpful in treating patients with cancer. In our opinion, the same applies to patients with acquired immune deficiency syndrome (AIDS) requiring intravenous medication and/or parenteral nutrition, although the infection rate of the catheters is considerably higher in these patients because of the underlying disease[1].

Over a 3-year period between December 1989 and December 1992 we implanted 27 Port-a-Cath devices (Pharmacia, Uppsala, Sweden) via the internal jugular vein in 24 male patients with AIDS. Twenty-one patients suffered from cytomegalovirus (CMV) retinitis, one from cryptococcal meningitis and two needed parenteral nutrition. In patients with CMV retinitis the relapse rate of 100 per cent can be reduced significantly by parenteral prophylaxis with ganciclovir or foscarnet[2,3].

Preventing the blindness that usually develops within weeks improves the quality of the remaining life (mean duration 8·5 months). Furthermore, 20 patients were treated in a nursing home or outpatient setting, thus reducing costs of therapy[4]. The infection rate was considerably higher than in patients with cancer (0·31 infections per 100 catheter-days). The mean length of catheter function was 157 days.

Our experience shows that patients with AIDS clearly benefit from fully implantable venous access systems, with improved quality of life and reduced hospital stay.

Oesophagectomy by a transhiatal approach or thoracotomy: a prospective randomized trial

Sir

We read with interest the recent study by Dr Goldminc and colleagues (*Br J Surg* 1993; **80**: 367–70) comparing the results of transhiatal resection with a right thoracotomy approach in oesophagectomy for carcinoma. The operative technique for the right thoracotomy method was not detailed but a reference was given to an earlier paper[1]. This in turn mentions a number of techniques, although the authors latterly appeared to favour the Akiyama[2] procedure, an extensive operation involving laparotomy, right thoracotomy and neck exploration.

We would like to draw attention to an operation that appears to have been largely forgotten, namely the right thoracotomy alone without laparotomy first described by Belsey and Hiebert[3]. Although it does not allow for a wide clearance of the lymphatic drainage, we have found that the duration of survival does not appear to be compromised. Indeed, Dr Goldminc demonstrated almost 100 per cent mortality by 36 months if the nodes were positive whichever of their operative techniques was employed. We believe that the exclusive right thoracotomy approach causes less trauma and is quicker to perform, allowing the unfit elderly population effective surgical palliation and occasional long-term cure.

Laparoscopic *versus* open appendicectomy: a prospective evaluation

Sir

I read with interest the recent correspondence from Mr Choy and colleagues (*Br J Surg* 1993; **80**: 399) detailing their early experience with laparoscopic appendicectomy. I am concerned about their stated policy in managing patients who undergo diagnostic laparoscopy for right iliac fossa pain and are found to have a macroscopically normal appendix. They report that the policy is 'as with open exploration, to remove the appendix irrespective of its macroscopic appearance', although the rationale for this is not immediately clear. Presumably, the main reason is the difficulty in correctly diagnosing acute appendicitis, or lack of it, from the macroscopic appearance alone. Indeed, a histopathological study[1] has shown that 19 per cent of appendices described by the clinician as macroscopically normal were found to have histological features of acute appendicitis. In addition, 8 per cent of appendices thought to be acutely inflamed were found to be histologically normal. Discrepancies will exist between surgeons' opinions as to whether an appendix looks normal or is inflamed, and a negative appendicectomy rate by the laparoscopic approach will always occur. However, these figures do not necessarily justify the removal of a macroscopically normal appendix, especially if other lower abdominal or pelvic pathology is encountered. In addition, it is well known that the risk of complications of an operation increases with each additional procedure. The stated policy may also cause diagnostic confusion for a future clinician, bearing in mind that not all patients remember what operative procedure has been performed on them. A small scar in the right iliac fossa is accepted as proof that appendicectomy has previously been performed, but a 1-cm subumbilical laparoscopic scar does not imply the same. The case for preserving a normal appendix has previously been made[2].

2. Wheeler RA, Malone PS. Use of the appendix in reconstructive surgery: a case against incidental appendicectomy. *Br J Surg* 1991; **78**: 1283–5.

Authors' reply

Sir

We would like to thank Mr Eriksen for his interest in our report and his useful comments. In a recent report of our early experience[1], we acknowledged that the policy of appendicectomy irrespective of macroscopic appearance is controversial. However, we believe that this is the safest course of action given the discrepancy between macroscopic appearance and histology[2,3]. Diagnostic confusion may arise in future regardless of the policy adopted[4] and may be reduced if appendicectomy is performed in all cases. Although the use of the appendix in reconstructive surgery is well established, relatively few patients require such procedures and we have to balance this against the risk of subsequent appendicitis and its complications. We believe laparoscopic incidental appendicectomy is justified as it can be performed safely and quickly without using expensive disposables.

Two of the tables in the above Review contained numerical errors. In *Table* 5, the entry in column three for Soper *et al.*[62] should read 618. In *Table* 6, the entry in column five for Western General Hospital, Edinburgh, should be 4·2 per cent. Apologies to the reader for any confusion caused.

Book reviews

Musculoskeletal Surgery for Cancer – Principles and Techniques

P. H. Sugarbaker and M. M. Malawer (eds). 285 × 220 mm. Pp. 391. Illustrated. 1992. New York: Thieme Medical. DM 198.

For those familiar with the *Atlas of Extremity Surgery* (J. B. Lippincott, 1984) this expanded volume under its new title will be greatly welcomed. No book on musculoskeletal tumours will cover the whole field nor will it include all practices and opinions. This volume deals with tumours of the shoulder and pelvic girdles together with those of the extremities. It does not cover the spine.

A text of 120 pages deals with the clinical presentation, assessment and staging of soft tissue and bone tumours. There are useful sections on phantom limb pain and rehabilitation, together with an overview of chemotherapy and radiotherapy. The remaining 260 pages comprise an atlas of operations, clearly described and with excellent drawings. Each chapter is preceded by a summary. I would commend this well written book to orthopaedic surgeons in training. It is up to date and the references are topical. Naturally, it reflects the practice at one particular centre. For limb-sparing surgery, prosthetic replacement is covered but allografts not.

More importantly, this volume should have a prominent place on the shelves of all orthopaedic departments. It clearly states the dangers of inexpert treatment; any orthopaedic surgeon faced with a tumour is well advised to read this book. There is much at stake for the patient, and for best results tumour surgery should be performed at expert centres.

An Aid to Paediatric Surgery. 2nd ed.

R. A. MacMahon (ed.). 240 × 189 mm. Pp. 267. Illustrated. 1991. Australia: Churchill Livingstone. £15·95.

This new edition to *An Aid to Paediatric Surgery* is welcomed as it provides an excellent concise account of the essentials of paediatric surgery for medical students and paramedical staff. It achieves its aims in a volume of 260 pages, is well laid out and easy to read. It is a multiple-author book with the majority of the contributors coming from Monash University in Melbourne, but with the editor being responsible for seven of the chapters there is a pleasant uniformity of style.

There are new chapters on child abuse, sports medicine and ethics. There has been a revision of methods of investigation to include computed tomography and magnetic resonance imaging where appropriate. The illustrations, including the diagrams, are simple and clear, and at the end of each chapter there is a short list of references for further study.

Although this volume is intended for medical students, it would also provide a handy reference for paediatric medical and surgical house staff. The editor is to be congratulated on this new edition, which is thoroughly recommended for medical students during their paediatric training.

Long-term Results in Vascular Surgery

J. Yao and W. Pearce (eds). 266 × 188 mm. Pp. 494. Illustrated. 1993. Norwalk, Connecticut: Appleton and Lange. US$125.

This 500-page book is a compendium of 40 chapters, all written by different authors, dealing with virtually every aspect of peripheral arterial and venous surgery. The excellent first chapter by Rutherford summarizes the problems in reporting long-term results of vascular operations and suggests some solutions. The book is worth looking at for this chapter alone, which is a model of clarity and sound logical and statistical advice. In general these principles are followed in the many subsequent chapters describing the results of specific procedures, although there are a few where the presentation of data seems biased in favour of the author's preferred position.

Inevitably, there is some overlap between individual chapters and some authors have strayed from the book's original purpose by describing in detail surgical procedures that they favour. Despite these minor shortcomings, the editors have brought together a unique set of reports on the long-term results of vascular operations, making this an ideal reference work. It highlights one of the biggest problems of vascular surgery: the remarkable rarity of large, properly designed, prospective, randomized trials comparing alternative procedures for specific lesions. Despite the large number of descriptive series with long-term follow-up, the uncommitted surgeon will still find it difficult to decide which of several established techniques gives the best results in a particular situation.

The chapters are written mainly by surgeons and there is little mention of adjuvant pharmacotherapy to attempt to improve the results of surgery. There is now quite good evidence that antiplatelet drugs improve the results of most types of vascular surgery, but their use is mentioned only briefly. This book will be an important reference work in all specialized departments of vascular surgery.

Vascular Diseases in the Limbs – Mechanisms and Principles of Treatment

D. L. Clement and J. T. Shepherd. 271 × 186 mm. Pp. 319. Illustrated. 1993. St Louis, Missouri: Mosby–Year Book. £57.

Clinicians dealing with vascular disease have forged important links with scientists both in the development of investigations and in experimental work on the pathophysiology of such disease. This book aims to 'provide a bridge between current fundamental and clinical knowledge of blood vessels and their diseases'.

The potential diversity of readership has resulted in a mixture of chapters of widely varying detail and emphasis. There are general chapters on the basic mechanisms of disease that could provide good background reading for a vascular surgical trainee or refresh the memory of his arteriosclerotic mentor. Sadly the 'surgical' content of the book is otherwise rather sketchy and not detailed enough for an aspiring vascular surgeon. There is considerable emphasis on disease of the microcirculation with three chapters on vasospastic disorders and a good critique on methods for assessing the small blood vessels. By contrast, the book covers many investigative methods for large-vessel disease more as a catalogue than with critical or helpful guidance about their place in management.

The interested scientist may find this book helpful to dip into for an overview of surgical practice, and for trainees in vascular medicine it is probably a useful primer. Surgeons are likely to require more detailed texts on investigation and treatment of vascular disease, except for the sections on the microcirculation. Their level of interest in this subject will depend on whether they yet work in cooperation with a vascular physician interested in the microcirculation, who should allow his surgical colleagues to concentrate their expertise on managing disease of the larger blood vessels.

Instructions to authors

The British Journal of Surgery publishes original articles, reviews and leading articles. Short notes, case reports and surgical workshops are also accepted. All manuscripts are submitted to editorial review.

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another journal, has not been accepted for publication elsewhere and has not already been published. **Any detected attempt at dual publication will lead to automatic rejection and may prejudice acceptance of future submissions.** Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title page should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies of original articles and other editorial matter to: The Senior Editor, *The British Journal of Surgery*, Blackwell Scientific Publications Ltd, 25 John Street, London WC1N 2BL, UK. Telephone: 071-404 1831. Facsimile: 071-404 1927.
Books for review should be sent to the same address.

A covering letter must accompany all submissions and must be signed by all authors. The covering letter should state if an abstract of the work has been published and whether the authors wish the manuscript and/or illustrations to be returned if the work is not accepted. The first named author is responsible for ensuring that all authors have seen and approved the manuscript and are fully conversant with its contents.

Rejected manuscripts will not be returned to the authors, unless this is specifically requested.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached. Written consent must be obtained from the patient, legal guardian or executor for publication in *The British Journal of Surgery* of any details or photographs which might identify an individual. Evidence of such consent should be submitted with the manuscript.

Preparation of manuscripts

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65, or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from The Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR, UK (cost £1·00 per copy).

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. **When quoting specific materials, equipment and proprietary drugs, authors must state in parentheses the name and address of the manufacturer.** Failure to do so will result in delay in publication as the Journal considers that this information is essential for any reader who wishes to obtain similar material. Generic names should normally be used.

Original articles

Original articles should normally be in the format of introduction, methods, results, discussion. Each manuscript should contain a summary on a separate page. Authors are reminded that there is considerable pressure on editorial space in the Journal. Lengthy manuscripts are likely to be returned to authors for shortening. The discussion in particular should be clear and concise, and should be limited to matters arising directly from the results. Authors should avoid discursive speculation.

Reviews

The Editorial Board of *The British Journal of Surgery* encourages submission of review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium. Potential authors seeking advice on the suitability of review topics are advised to contact: Mr J. A. Murie, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Leading articles

The Editors commission signed leading articles to *The British Journal of Surgery*. These articles are 600–1000 words in length, address controversial topics of current interest and are supported by key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium is payable on publication.

Short notes

These are original observations presented in brief form. They should follow the standard format of introduction, methods, results and discussion, but no summary is required. Short notes should not exceed 500 words with a maximum of five references and one table or one figure.

Case reports

The British Journal of Surgery receives an increasing number of case reports each year. Space within the Journal remains at a premium and the rejection rate is high. Case reports should be no more than 400 words (300 if accompanied by a figure), with no more than five references and one illustration.

Surgical workshops

These describe technical innovations or modifications which may be useful in surgical practice. These articles should be less than 500 words long; they may be accompanied by no more than two figures and up to five references.

Typescripts

It is *essential* that manuscripts be clearly reproduced with adequate space for editorial notes. **Papers must be typewritten or printed on A4 paper (210 × 297 mm) on one side of the paper only with double spacing and 4 cm margins. Manuscripts which do not conform to these requirements will be returned to the authors for recasting.** Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations. The text should usually follow the standard sequence of introduction,

methods, results and discussion. These sections should run sequentially through the text, avoiding blank space between them.

Title page

The title page should give: (1) the title of the article; (2) the name and initials of each author; (3) the department and institution to which the work should be attributed; (4) the name, address, and telephone and facsimile numbers of the author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; and (6) the category in which the manuscript is being submitted (original article, case report etc.).

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytical methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Three copies of all illustrations and tables should be submitted. Each table with an appropriate brief title should be typed on a separate page. At least one set of illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Photocopies should be of sufficient quality to enable the Journal's referees to judge their content and value. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers of patients involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full. Permission to use published work must be obtained from the original author and the publisher before submission.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text and must be clearly defined on first use.

Numbers and units

The decimal point, not a comma, is used, e.g. 5·7. A space and not a comma follows thousands and multiples thereof, e.g. 10 000. SI units (International System of Units) should be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

References

References should be typed with double spacing and cited in the Vancouver style (see above: Uniform Requirements for Manuscripts Submitted to Biomedical Journals). Reference to abstracts from meetings is discouraged; reference to unpublished communications is not acceptable. Personal communications should be cited in the text, in parentheses. The first author is responsible for confirming the acceptability of the material quoted with the originator.

In the text, references should be numbered consecutively by superscript: ^{1,2} or $^{1-3}$. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication; volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; **66**: 184–6. The sequence for the chapters of a book should be: author(s); chapter title; editors; book title; place of publication; publisher; year of publication; page numbers. For example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In: Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer-Verlag, 1981: 123–63.

Statistics

For detailed guidance on the handling of statistical material, authors should consult *The British Journal of Surgery* 1991; **78**: 782–4. The Editors and statistical referees in evaluating a manuscript will consider the *design* of the study, the *presentation* of the data, the *analysis* of the data, and the *interpretation* of the results.

Design

Authors should set out clearly the objectives of the study, should identify the primary and secondary hypotheses, and should explain the rationale for the choice of sample size.

Presentation

Whenever possible a graphical presentation should be used to illustrate the main findings of a study. The use of standard deviation and standard error should be clearly distinguished. The use of the '±' symbol should be avoided; these statistics should be presented in parentheses after the mean value.

Analysis

There should be a clear description of which methods were used for which analyses, and any methods not in common usage should be supported by references. Results of statistical tests should be reported by stating the value of the test statistic, the number of degrees of freedom and the P value. For example, '$t = 1{\cdot}34$, 16 d.f., $P = 0{\cdot}20$' might be reported. Actual P values should be reported, to two decimal places, especially when the result is not significant, rather than stating 'not significant'.

Whenever possible, the results of the primary analyses should be reported using confidence intervals instead of, or in addition to, P values.

Interpretation

Statistical significance should not be confused with clinical significance. In particular, 'negative' findings should be interpreted through the use of confidence intervals.

Authors should beware of placing undue emphasis on secondary analyses, especially when they were suggested by an inspection of the data.

COMPLICATIONS OF LAPAROSCOPY AND HYSTEROSCOPY

Edited by R S Corfman, M Diamond and A DeCherney

086542201X, Hardback, £45.00, Jan-93,
288 pages, 86 illustrations

Many surgical procedures in gynaecology are now performed by means of endoscopy or 'keyhole surgery' rather than by traditional surgery, thereby reducing hospital stays and cutting costs. The number and difficulty of such procedures is growing constantly. This book deals with potential complications of such techniques and how to avoid and rectify them.

The contents deal with all the major procedures, including sections on: preoperative and postoperative considerations, anesthesiology, intraperitoneal insufflation and trocar placement, complications arising from vaginal placement of accessories, operative laparoscopy, specific gynecological procedures, hysteroscopy, general surgery and other surgical complications. Their complications are addressed in detail to help the practitioner better understand each procedure and its potential problems.

- covers all the major procedures;
- deals with increasingly popular and complicated techniques;
- enables the practitioner to operate more safely;
- responds to the growing trend towards day case surgery.

Practical Laparoscopy

A G Gordon and P J Taylor

0632036583, Hardback, £29.50, Apr-93,
176 pages, 94 illustrations

General surgery and the surgical specialities are being revolutionised as the application of minimally invasive techniques becomes widespread through all grades. The laparoscope has been and remains at the forefront of minimally invasive procedures both as a diagnostic tool and now more frequently for operative procedures.

This book conveys in a didactic and succinct way the principles of laparoscopic procedure for the younger trainee and the older surgeon approaching the technique for the first time.

- a practical 'how to' book;
- includes descriptions and line drawings of operative techniques;
- emphasis on training and safety;
- information on facilities and equipment required;
- an inexpensive introduction to a technique growing in popularity.

Contents:

Introduction; Instruments; Diagnostic Laparoscopy; Principles of Operative Laparoscopy; Simple Laparoscopy Surgery; Complex Laparoscopy Surgery; Christopher Roysten; Complications; Safety and Training; Facilities for Laparoscopic Surgery; Anaesthesia

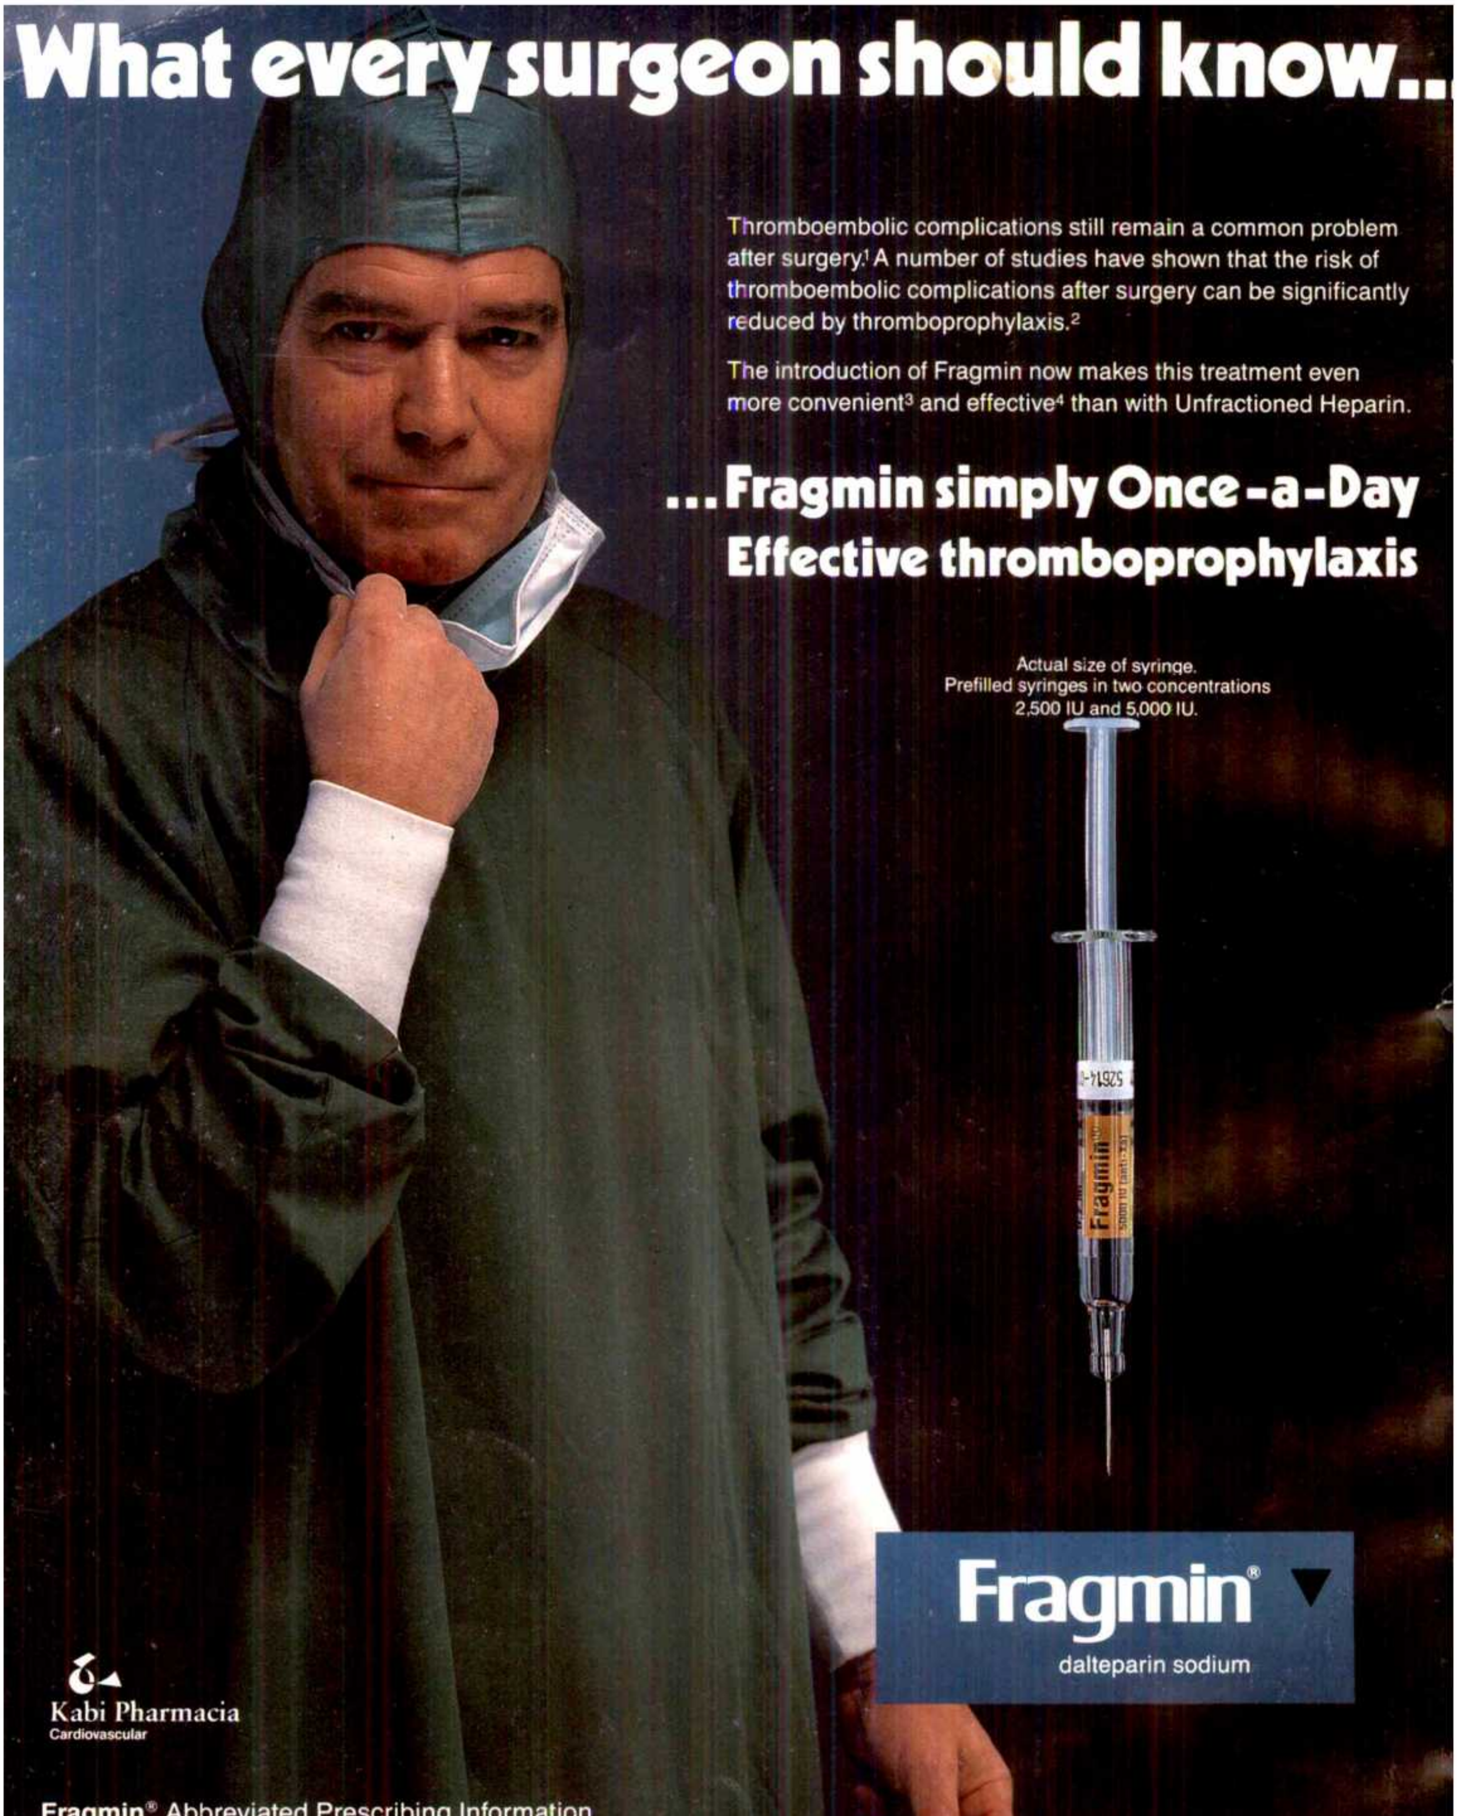
Osney Mead, Oxford OX2 0EL, UK Tel: (0865) 240201

What every surgeon should know...



Thromboembolic complications still remain a common problem after surgery.[1] A number of studies have shown that the risk of thromboembolic complications after surgery can be significantly reduced by thromboprophylaxis.[2]

The introduction of Fragmin now makes this treatment even more convenient[3] and effective[4] than with Unfractioned Heparin.

...Fragmin simply Once-a-Day Effective thromboprophylaxis

Actual size of syringe.
Prefilled syringes in two concentrations
2,500 IU and 5,000 IU.

Fragmin®
dalteparin sodium

Kabi Pharmacia
Cardiovascular

Fragmin® Abbreviated Prescribing Information.

Presentation: Single dose disposable syringes containing dalteparin sodium 2,500 IU (anti-Factor Xa)/0.2 ml or 5,000 IU (anti-Factor Xa)/0.2 ml. No preservative present. **Indication:** Peri- and post-operat
surgical thromboprophylaxis. **Dosage:** Adults only. Moderate risk of thrombosis. Fragmin 2,500 IU administered subcutaneously (sc) 1—2 hours prior to surgery and thereafter 2,500 IU sc once-daily for f
days or until the patient is fully ambulant. High risk of thrombosis eg elective hip replacement, extensive operations, patients with malignant disease. Fragmin 2,500 IU administered sc 1—2 hours prio
surgery, and the same dose is administered 12 hours later. Thereafter 5,000 IU sc once-daily for five days or until the patient is fully ambulant. **Contraindications:** There are no known absolute contraindicati
to Fragmin. However, caution should be exercised in patients with an increased risk of bleeding complications. **Precautions:** Caution in patients with severely disturbed hepatic or renal function, thro
bocytopenia, or defective platelet function and in patients receiving drugs affecting coagulation/platelet function; patients with known heparin hypersensitivity. Fragmin, when administered in doses
2,500—5,000 IU/day, does not generally accumulate and, therefore, monitoring of anti-Factor Xa levels is not usually necessary. **Side effects:** High doses of Fragmin with serum anti-Factor Xa levels grea
than 1.5 IU/ml may cause bleeding. Transient slight to moderate increase in liver enzymes have been observed. The following heparin side effects cannot be excluded as Fragmin is a derivative of hepa
thrombocytopenia, allergic reactions, osteoporosis. **Overdose:** 100 IU Fragmin is inhibited by 1 mg protamine: see data sheet for full prescribing information. **Legal Category:** POM. **Packs:** Fragmin 2,5
IU/0.2 ml; pack of 10 single dose syringes. 5,000 IU/0.2 ml: pack of 10 single dose syringes. **P L Numbers:** 2,500 IU/0.2 ml 0022/0076. 5,000 IU/0.2 ml 0022/0077. **Kabi Pharmacia Ltd, Davy Avenue, Knowlh**
Milton Keynes, MK5 8PH.

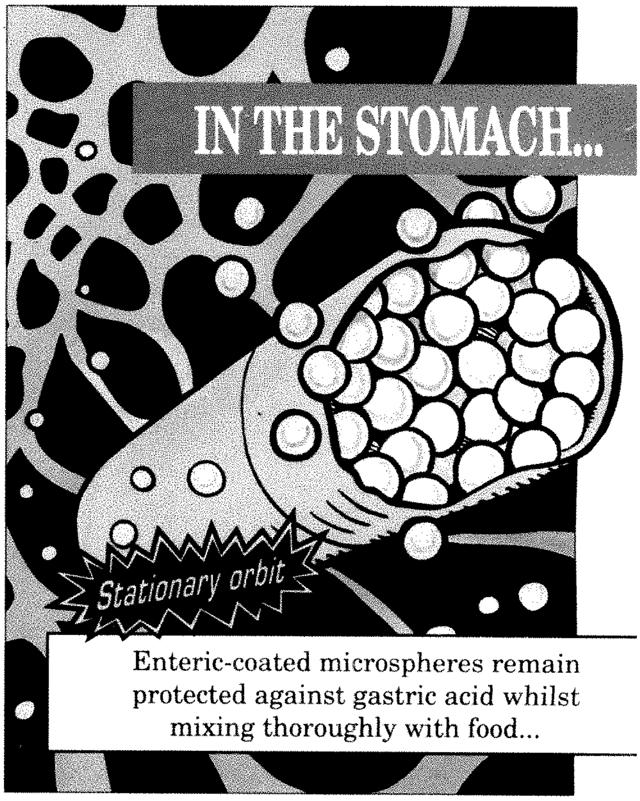
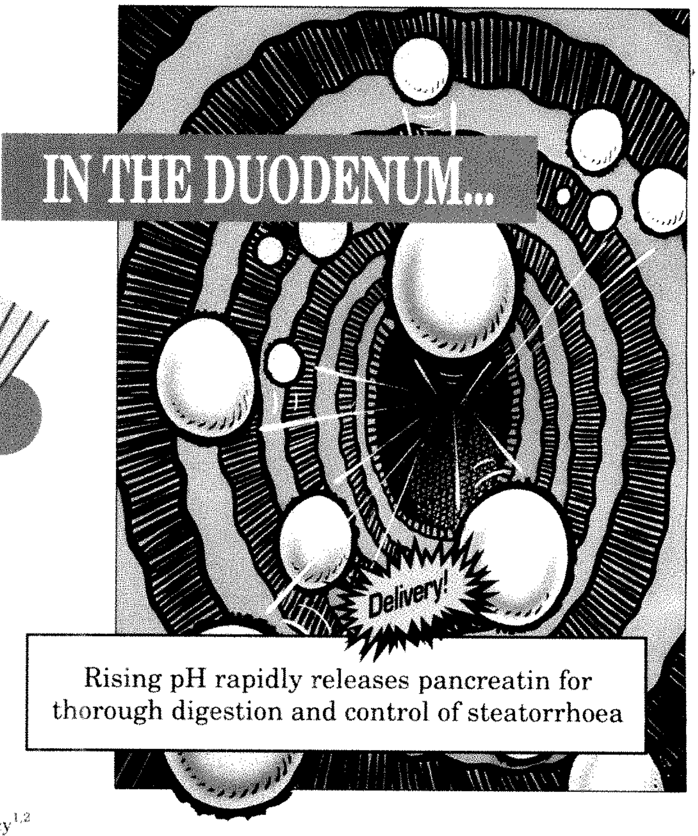
A REAL FORCE IN PANCREATIC EXOCRINE INSUFFICIENCY



Enteric-coated microspheres remain protected against gastric acid whilst mixing thoroughly with food...



IN THE DUODENUM...
Delivery!

Rising pH rapidly releases pancreatin for thorough digestion and control of steatorrhoea

creon®
pancreatin 25000

Superior control of steatorrhoea†

† Compared with standard enteric-coated tablets in pancreatic insufficiency[1,2]

Prescribing Information

Presentation: Opaque orange/yellow hard gelatin capsules containing brownish coloured enteric coated pellets of pancreatin, equivalent to:
25,000 PhEur. units of lipase
18,000 PhEur. units of amylase
1,000 PhEur. units of protease (total)
Available in packs of 50. Basic NHS price £19.50

Indication: Pancreatic exocrine insufficiency

Dosage and Administration: Adults (including elderly) and children: Initially one capsule with meals, then adjust according to response. The capsules can be swallowed whole, or for ease of administration they may be opened and the granules taken with fluid or soft food, but without chewing. If the granules are mixed with food it is important that they are taken immediately, otherwise dissolution of the enteric coating may result.

Contra-indications, Warnings, etc. Contra-indications: Substitution with pancreatic enzymes is contra-indicated in the early stages of acute pancreatitis. Warnings: Use in pregnancy: There is inadequate evidence of safety in use during pregnancy. The product is of porcine origin. Rarely cases of hyper-uricosuria and hyper-uricaemia have been reported with very high doses of pancreatin. Overdosage although not experienced until now, could precipitate meconium ileus equivalen Perianal irritation, and rarely, inflammation, could occur when large doses are used.

FOR THE SERIOUS RESEARCHER

ROODEPLAAT RESEARCH LABORATORIES OFFER YOU......

- Pharmacokinetic, pharmacodynamic and toxicological studies in large laboratory animals, specialising in cardiovascular, neuropharmacology and male fertility (semen quality).
- Fully equipped theatres, including well organised anaesthetic, X-ray and intensive care facilities for research on non-human primates and dogs.
- Superb facilities as a research and training centre for minimal invasive surgery.
- Support by our own, modern, well-equipped laboratories for clinical biochemistry, haematology, blood gas analyses and microbiology.
- Metabolic studies in different animal species.
- All enquiries and projects are handled in strict confidence

All work is done according to OECD guidelines for GLP.

Relied upon by leading surgeons, Swann-Morton blades are as worldwide as their reputation for quality.

Alongside their classic surgical range, there are the "Major" orthopaedic blades, "Minor" disposables, and special blades for cervical biopsy and myringotomy. Most recent is the completely new "Fine" range.

Extensively researched, all blades are produced under strict quality control by precise automation, and inspected at every stage.

Swann-Morton always have the blade for the task, uniformly correct in shape, size and weight, and durably sharp – that's why they are famous worldwide!

The Practical Aspects of Laparoscopic Fundoplication

3 day course
directed by Professor Cuschieri
24th~26th November 1993
Course fee £1200.00

The course covers the practical aspects of both partial and total laparoscopic fundoplication using small group format and personal tuition.

Participants have the opportunity to:

- **Observe a live operative procedure with simultaneous commentary by Professor Cuschieri**
- **Perform both a total and partial procedure using the skills unit simulators and under the guidance of Professor Cuschieri**
- **Discuss the practical clinical details**
- **Review, on video, a variety of the cases carried out in Dundee**

For further information and dates later in the year contact:

Pocket Consultant in Gastroenterology

Pocket Consultant Series

S P L Travis, R H Taylor and J J Misiewicz

Pocket Consultant in Gastroenterology is a concise, practical guide to management in gastroenterology. It is directed to general practitioners, senior house officers and house officers and is intended to help the person on the spot to deal with practical issues of investigation and treatment. The book takes a sequential regional approach to the gastrointestinal tract. Clinical features, causes, investigation and management are systematically reviewed, with regular use of bullet points. The text is well-illustrated; clinical photographs are accompanied by line diagrams which speed understanding.

- includes problem-oriented chapters on Inflammatory Bowel Disease and gastrointestinal infection;
- the chapter on Procedures and Investigation contains a 'Houseman's Checklist';
- therapeutic diets are included in the chapter on nutrition;
- 'Diagnostic Dilemmas' are covered in the appendices.

432 pages, 45 illustrations, October 1991, £15.95, 0-632-01098-3

Overseas Members of the Editorial Board

Br. J. Surg. 1993, Vol. 80, October, 1225–1226

Further Board Members from around the world.

DR HIRAM POLK JR
(USA)

Hiram C. Polk Jr, who was born in 1936, has been Professor and Chairman of the Department of Surgery at Louisville, Kentucky, for the past 22 years. He graduated from Harvard and trained in St Louis and Miami. He was appointed Editor of *The American Journal of Surgery* in 1986. Among other distinctions, he has been President of the Society for Surgery of the Alimentary Tract and the Society of University Surgeons. His clinical interests embrace oesophageal surgery and the immunology of infection.

PROFESSOR RAJ NAMBIAR
(Singapore)

Raj Mohan Nambiar was born in India in 1934 and trained in India, England and Singapore. He gained Fellowship diplomas in England, Scotland and the USA. He is a senior consultant and Head of the Department of Surgery at Singapore General Hospital, and Clinical Professor of Surgery at the National University of Singapore. He was Master of the Singapore Academy of Medicine from 1990 to 1992 and founding Editor of the *Southeast Asian Journal of Surgery*. He has wide-ranging interests within general surgery.

DR ALBERTO LAURENCE
(Argentina)

Alberto Ernest Laurence was born in 1915 in Buenos Aires, where his father (who was English) was practising as a dental surgeon. He trained in Buenos Aires, and from 1964 to 1981 served as Head of the Surgical Department at Buenos Aires British Hospital. He was President of the Argentine Association of Surgery in 1982 and awarded an Honorary Fellowship of The Royal College of Surgeons of England in 1989. His main clinical interests have been colorectal cancer and diverticular disease.

0007-1323/93/101225-02 © 1993 Butterworth–Heinemann Ltd

PROFESSOR ANDRE VAN RIJ
(New Zealand)

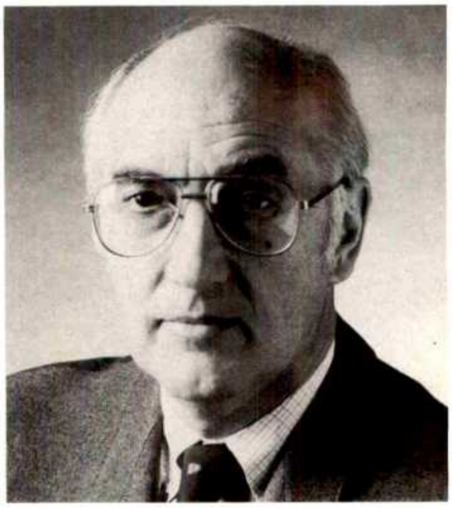
Andre M. van Rij (born 1945) has been Professor of Surgery at the University of Otago, Dunedin, New Zealand, since 1985. Born in The Netherlands but educated in Otago, he graduated as a doctor in 1970 and obtained his FRACS diploma in 1978. His training included attachments in London and North Carolina. He is a vascular surgeon with particular research interests in the role of free radicals in vascular disease as well as surgical audit.

PROFESSOR E. Q. ARCHAMPONG
(Ghana)

Emmanuel Quaye Archampong (born 1933) has been Dean of the University of Ghana Medical School for the past 9 years. He qualified at University College Hospital Medical School in 1961 and trained in London, Leicester and Accra. He became Senior Lecturer (1972), Associate Professor (1976) and Professor (1978) at the University of Ghana Medical School. He is Editor-in-Chief of the *West African Journal of Medicine*; his special clinical interests are gastroenterological disease in the tropics and diagnosis of the acute abdomen.

DR BERNARD LANGER
(Canada)

Bernard Langer, who was born in 1932, is Professor and Chairman of Surgery at the University of Toronto. He trained in Toronto, Houston and Boston, and obtained his Canadian FRCS in 1961. He is President-Elect of the Society for Surgery of the Alimentary Tract, Vice-President (Surgery) of The Royal College of Physicians and Surgeons of Canada, and Treasurer of the World Association of HPB Surgery. He is interested in all aspects of liver surgery, including transplantation.



PROFESSOR ANTHONY WATSON
(Australia)

Anthony Watson (born 1941) was appointed Professor of Surgery in the University of Sydney at the Royal North Shore Hospital in 1990. Previously he had spent 15 years as a consultant surgeon to the Royal Lancaster Infirmary, UK. He is a Manchester graduate who trained at Cambridge and Cardiff. He has been both Moynihan Fellow of the Association of Surgeons and Hunterian Professor at The Royal College of Surgeons of England. His clinical interest is centred on the oesophagus and he has written widely on various aspects of oesophageal disease.

Robin Williamson

Br. J. Surg. 1993, Vol. 80, October, 1227–1228

Trauma centres

There is general agreement that trauma care in the UK should be improved and the present arguments are concerned solely with how this may be achieved. In 1988 the Royal College of Surgeons of England Working Party reported on the management of patients with major injuries and recommended setting up 25 trauma centres in the UK, one for each 2 million population and staffed by 24-h consultant cover[1]. A first step forward was the introduction of the American Advanced Trauma Life Support courses by the College for improving the training of doctors in trauma care[2]. In 1992 the Department of Health identified accident treatment as one of the six priorities for healthcare in the future. Financial support was given by the Department for four centres – Stoke-on-Trent, Hull, Preston and the Royal London Hospital – with subsequent evaluation of different aspects of their trauma systems. These have become *de facto* trauma centres, but that does not exclude other hospitals performing the same function. The subject of this article is trauma centres as recommended by the Royal College, but it must be emphasized that complete trauma care consists of prevention, treatment and rehabilitation; a total system is required. Treatment consists of prehospital care (depending on trained personnel as well as transport and communication) and care in hospital (depending on emergency room staff, theatres, intensive care units and all the professional personnel in the hospital). Trauma care does not belong to any one person or department.

Before the Working Party report, a study of 1000 deaths from trauma showed large and unacceptable variation in results between centres[3]. The 1000 patients were divided into half who died before reaching hospital and half who died from possibly avoidable causes in hospital. Prehospital deaths that were avoidable by better care at the scene were not studied, but the large number that occurred at the accident scene emphasized the importance of the ambulance service, its trained personnel, its communication system and its transport. Improvement in trauma care must include a closer integration of prehospital and hospital services.

The original plan for the 192 districts in England and Wales was to have one district general hospital and one acute emergency department per district. The aim that each accident and emergency department should have one or more consultants has never been realized. This system was supposed to provide uniformly good emergency care, but it is now criticized. Furthermore, there are suggestions that many of the accident and emergency departments in London should be closed and that the functions of two or three in a group could be centralized.

What is being done at this moment to improve trauma services? The Department of Health has accepted the criticism that improvement should occur but has neither agreed nor planned 25 trauma centres. Instead, it has commenced an evaluation of the four trauma centres at Stoke-on-Trent, Hull, Preston and the Royal London Hospital. Professor Brian Williams, director of the Medical Care Research Unit at Sheffield, was chosen to research these four systems so that the government could make logical decisions. The two main projects are, first, an evaluation of regional trauma care systems comparing Stoke with the 'normal' district general hospitals at Hull and Preston, and, second, an evaluation of the Royal London Hospital's enhanced Helicopter Emergency Medical Service[4]. The research group is interested in prehospital care, so there is a further arm of the London study which will assess the effect of land ambulances staffed by personnel with enhanced training (paramedics). The same team is undertaking another study of the West Country helicopter service in Cornwall and the Sussex Police Helicopter Emergency Service. Both of these differ from the Royal London Hospital helicopter service in that they do not have suitably trained doctors on board.

Endpoints of the evaluation are in terms of mortality and morbidity. Major Trauma Outcome Study-type information will be collected. Morbidity will be recorded using global instruments of disability and correlated with the original trauma severity, measured by the North American Anatomical Injury Severity Score, and the physiological response, using the Revised Trauma Score.

Costs will be assessed for all the hospital and transport systems. 'Marginal' costs of cases brought in by helicopter will be calculated adding the costs of this transport

0007-1323/93/101227-02 © 1993 Butterworth-Heinemann Ltd

system to those that would normally occur if the patient came to hospital by land ambulance. Cost–benefit will be calculated by matching costs and marginal costs with the benefit of improved care, taking into account death and the expense of disability to the individual, his or her family and society. The mathematics are daunting because the cost of the premature death of a young person from a road traffic accident is now calculated by the Department of Transport at about £700 000; this includes such items as widow's pension, child allowance, loss of earnings, loss of production and loss of tax paid to central government (the Department of Health does not accept this figure). A further assessment will be made of which particular factors are most important in each of the different trauma care systems under evaluation.

Evaluation of the Greater London system, which is the only fully integrated helicopter emergency medical system with a doctor and paramedics on board, will be completed early in 1994. The study of the Sussex and Cornwall air ambulances, which are not directed specifically at trauma, will be completed later. The Stoke, Hull and Preston evaluation was started only in 1992 and will not be ready until 1994–1995. It should be understood that these three centres are not typical district general hospitals because all three have in-house neurosurgery units. Another difference is that Stoke has a team of six consultants who provide continuous 24-h cover for the 168-h week. If results vary between different systems, details must be examined to include prehospital transport, on-scene treatment and call-out systems.

The following statements are offered as a basis for discussion before decisions are made about building the suggested 25 trauma centres. The Department of Health evaluations will be ready in 1994–1995 and should provide the data needed for informed decision making.

1. Trauma care should include prevention, treatment and rehabilitation.
2. Treatment includes prehospital care, with rapid transport by land ambulance or helicopter and highly trained ambulance personnel with or without doctors, and care in a hospital that has all the local acute district general hospital services and immediate access to essential regional specialties by fast secondary transport.
3. Prehospital treatment saves lives by avoiding death from respiratory or circulatory causes. This must be improved and the paramedics integrated into the hospital services.
4. Hospital care may result in death from an avoidable cause. Early surgery and adequate intensive therapy are essential. Consultant-led teams experienced in multiple trauma should be encouraged.
5. Since the majority of hospital deaths result from head injuries, a neurosurgical unit should be associated with every trauma centre. The corollary is that no neurosurgery unit should exist in isolation from an acute general hospital.
6. All neurosurgical and other specialist units (burns, maxillofacial, cardiothoracic, transplantation) should have helipads to facilitate secondary transport. Ideally they should be integrated into acute hospitals.
7. Closure of some hospitals, and accident and emergency departments may eventually lead to others taking on the form of a trauma centre, with the essential specialty mix. This does not imply a UK network of expensive new trauma centre hospitals.
8. The ideal system of trauma care has not yet been agreed but any improved system should exist on a national scale, be available to the whole population and be paid for by the National Health Service.

Laparoscopic surgery for colorectal cancer

There are two authors of this article because it is necessarily a debate, the gift of reliable prophecy being in general denied even to surgeons. The laparoscopic revolution is rocking the foundations of our institutions and changing every branch of general surgery. It is now urgent that its scope and limits should be defined.

A recent BBC *Newsnight* programme, not sharing our diffidence about prophecy, told the public that 80 per cent of abdominal operations will soon be performed through the laparoscope. The younger author (N.A.O'R.) is impatient to conquer the remaining 20 per cent; the older (R.J.H.) has difficulty believing that the most demanding procedures will ever be better performed without conventional open exposure. The virtual loss of tactile input, the reduced ability to apply direct pressure to control bleeding or to retract powerfully to display tissue planes, the current limitations of two-dimensional video, and the tedious completion of a knot that would formerly have taken seconds, all appear to the senior author to be insurmountable obstacles. Is he in danger of becoming a 'beached whale', his world inherited by the 'young lion' with the laparoscope?

Despite the misgivings of many, demanding colorectal laparoscopic surgery is being performed, in Britain and around the world, for both benign and malignant disease[1–3]. The required skills and training are considerable and the 'learning curve' daunting. All agree that simpler procedures must precede surgery for cancer; rectopexy and colonic resection for benign disease allow surgeons to refine techniques of dissection and to observe for themselves the essential steps of precise rectal mobilization. But is laparoscopic colorectal cancer surgery really worth all the time and expense? Can the young lion persuade the beached whale?

Abdominoperineal operations can now be performed without a significant abdominal incision, anterior resection with only a 5-cm wound. Patients have less pain, mobilize sooner and appear to suffer less paralytic ileus and fewer infective problems; but are we sacrificing long-term survival for the sake of a little less pain? We do not yet know local recurrence rates after these new procedures but it seems sensible to assume that long-term outcomes will depend on adherence to established oncological principles. We both believe that resection of a precisely defined tumour package around the primary lesion is the chief determinant of surgical cure[4]. Careful dissection is needed, as is reasonably proximal pedicle ligation and the prevention of abdominal or staple-line contamination by luminal contents. An unprotected specimen must not be squashed against parietal tissues on removal.

Dissection with the laparoscope should be identical to that achieved at open operation. We agree with Monson *et al.* that the view low in the pelvis may even be better using the laparoscope, but this is not always so as it is easy to stray into the mesenteric fat and create irksome bleeding that can render accurate dissection impossible[1]. Access to the 'holy plane' of rectal surgery can readily be achieved posteriorly and anteriorly, but staying in the plane laterally can be difficult[5]. Herein lies the basic message: if an accurate tumour excision cannot be done, conversion to an open procedure must be the rule. The surgeon's good judgement should be applauded rather than surgical timidity condemned.

Instrumentation for minimally invasive surgery is becoming both better and more expensive all the time. Use of reusable tools must be encouraged. An extra expenditure of between £500 and £1000 is required to fashion an intracorporeal laparoscopic anastomosis after dividing both bowel and vascular pedicle with cutting staplers. The proximal extent of vascular and lymphatic clearance should be the same as that achieved by open surgery. Spillage of luminal contents must be avoided; cutting staple guns can reasonably isolate bowel contents but they may also increase suture-line recurrence by crushing downstream tumour cells into the staple line. A triple-staple technique might facilitate intraluminal washouts below the first staple line and so guard against implantation, as we believe to be necessary[6].

The present generation of laparoscopic staple guns does not always allow low rectal division, especially in the narrow pelvis. We are concerned by the high percentage of abdominoperineal operations in a recent unselected series[2]. One would hope that this reflects an unusual referral pattern and not a tendency to take the easy way out and create a 'minimally invasive sphincter sacrifice'. It may be that ultralow and even low anterior resection for middle- and lower-third rectal carcinoma should remain in the domain of conventional surgery. Considering his

0007-1323/93/101229–02 © 1993 Butterworth–Heinemann Ltd

special interest operation – total mesorectal excision – the senior author can see no alternative to finger and thumb compression of the rectum just distal to the palpable lower edge of the tumour. This is essential before accurate placement of a clamp across the muscle tube beyond the mesorectal 'capsule' of tissue prior to cytocidal washout. This technique has made possible 50 'close shave' sphincter-saving procedures in Basingstoke for lesions 4–6 cm from the anal verge[7].

The prolonged duration of laparoscopic procedures is a major concern. Not only do they take up valuable and often scarce list space but 6–8-h operations must increase the risk of thromboembolic complications. Experience does shorten operating times but even highly skilled surgeons may find progress painfully slow. Once again, judgement is required and conversion to open operation in such circumstances is often prudent. Once resected, the specimen should have a clean mesenteric edge and leave an empty tumour bed. Lymph node counts are reported and laudable but may not tell the whole story[1,2]. A ragged or shredded specimen may contain more lymph nodes but must imply a greater risk of residual tumour or intraperitoneal seeding. It may be that a photographic record coupled with better margin examination such as that suggested by the pathologists Quirke and colleagues[8] will give a more reliable indication of the adequacy of cancer clearance.

As first noted by Fielding *et al.*[9], variability among surgeons is obvious in terms of local recurrence of rectal cancer, rates of 5–40 per cent being reported. One may expect that laparoscopic procedures will have a similar spread but it will be a tragedy if poor outcome is perpetuated for the sake of smaller incisions. Unfortunately, such surgical variation devalues the potential worth of a multicentre trial, but laparoscopists must strive to achieve the excellent results now being produced by experienced rectal operators, and the new methods must be audited by every practicable method. A prospective register of all patients *without exclusion* is overdue; the public is ill served by the under-reporting of mishaps for fear of ridicule or litigation.

No surgeon should embark on a laparoscopic operation for cancer until he or she has watched and been convinced by pictures of satisfactory dissection and 'emptied' tumour beds on the video screen by those who advocate the method. With the arrival of sophisticated electronic imagery, it has never been easier for one surgeon to show another exactly what has been achieved. Despite considerable personal experience and having observed many international experts, neither of us has yet seen or reproduced proper total mesorectal excision laparoscopically. The senior author remains unhappy even at the cancer clearance achieved at more proximal colectomies. A recent warning by Wexner[10] that four separate port recurrences have been publically reported after resection of Dukes' A or B carcinoma suggests that tragedies may be occurring in the wake of the new technology.

Certain laparoscopic techniques can benefit patients with cancer. Palliative resection, abdominoperineal excision 'top end', splenic flexure mobilization, reversal of Hartmann's procedure and stoma creation are obvious examples. When operating for cure, however, we cannot condone compromise of the established principles that have made colorectal cancer the one commonly curable visceral malignancy.

Complications of circumcision

N. Williams and L. Kapila*

Circumcision remains a common operation, with over 30 000 procedures performed annually in the UK, mostly on children. The British Medical Association has recommended that circumcision should be performed only for medical reasons. Despite this, controversy exists over whether too many circumcisions are being performed. Are patients being exposed to an unnecessary operation? It may be argued that in doubtful cases it is easier to proceed to circumcision on the assumption that the attendant risks are low, but the operation is associated with a definite morbidity and rare deaths have been reported. This review considers the spectrum of complications that may result from circumcision and discusses the possible aetiological mechanisms.

Circumcision is probably one of the oldest of all surgical procedures. Although the origin of the practice is not entirely clear, it almost certainly began as a religious rite. That it was practised by the Egyptians is evident as the earliest mummies were found to be circumcised. In the Jewish community circumcision remains a religious ritual and is usually performed on the child's eighth day of life by a *Mohel.* Religious circumcision is also practised by Muslims; the procedure is performed between the ages of 4 and 13 years. Curiously, however, the Koran contains no specific ordinance on this subject. Currently, approximately one-sixth of the world's male population is circumcised, mostly on religious grounds. In Western society circumcision is usually performed for medical reasons, the commonest of which is phimosis[1-3]. There is, however, enormous variation between the circumcision rate in the UK (5-6 per cent[1,4]) and that in the USA (80-90 per cent[5-7]). This large discrepancy exists despite recommendations from both the British Medical Association[8,9] and the American Association of Pediatricians[10] that circumcision should be performed only for medical reasons.

The aim of circumcision is to excise sufficient foreskin (both penile shaft and inner preputial epithelium) to leave the glans uncovered. As an alternative to circumcision some advocate the technique of 'preputial plasty', where a longitudinal incision of the phimosis constricting band is followed by transverse suture[11]. Apparently more popular in Europe, it is a method that has yet to find favour among surgeons in the UK. There are many different techniques of circumcision but they can be broadly classified into four types: dorsal slit, shield, clamp and excision[12]. All these techniques have their strengths and limitations together with their protagonists and critics. More often than not, however, complications arise as a result of operator inexperience rather than of the method employed. All techniques aim to provide the best cosmetic result together with the lowest possible morbidity rate; in this respect the key factors to be observed are attention to asepsis, adequate but not excessive excision of the inner and outer preputial layers, haemostasis and cosmesis[12]. Some authors have reported a complication rate as low as 0·06 per cent[13], while at the other extreme rates of up to 55 per cent[14] have been quoted. This reflects the differing and varying diagnostic criteria employed; a realistic figure is 2-10 per cent[3,12,15]. Although haemorrhage and sepsis are the main causes of morbidity, the variety of complications is enormous. The literature abounds with reports of morbidity and even death as a result of circumcision.

Operative complications

Haemorrhage and sepsis are the commonest complications and are considered in greater detail below. The nature of circumcision dictates that errors of omission and commission, i.e. too little or too much, in assessing how much foreskin to remove are likely to happen, and one of the commonest complaints is of an unsatisfactory cosmetic result. If insufficient foreskin is removed the cosmetic appearance is such that the penis does not appear to have been circumcised; phimosis may still subsequently develop. In a series of consecutive circumcisions in Australia, Leitch[16] found that in 9·5 per cent of patients the operation had to be repeated because of inadequate skin excision at the initial procedure. MacCarthy *et al.*[17] reported this figure to be 1 per cent in a study from the UK. In a more recent series from Israel, where religious circumcision is widespread, of 60 children referred following potentially inadequate circumcision 42 required recircumcision; the majority of these children were operated on before 4 years of age[18]. The rest were treated conservatively and had a satisfactory cosmetic result at follow-up to 10 years of age. Insufficient excision of the foreskin and inner preputial epithelium may result in wound contraction and cicatrization of the distal foreskin. The fibrotic ring so produced may result in true phimosis, an event observed in 2 per cent of cases in one UK series[15]. In severe cases urinary obstruction may ensue[19].

Removal of too much skin from the penile shaft may be caused by pulling it over the glans during operation. After foreskin excision the remaining skin slides back, leaving a denuded shaft. Others suggest that such penile denudation injuries occur as a result of failure to break down the ventral foreskin adhesions to the glans penis completely[12,20]. It is therefore essential that, before any incision is made, the inner preputial epithelium is completely free from the glans such that the entire coronal sulcus can be visualized. Penile denudation injuries may occur as a result of sepsis[21], from diathermy injury[22] or from injected substances mistaken for anaesthetic solutions[22]. The majority of cases can usually be managed conservatively with a satisfactory cosmetic and functional outcome[21,23-25]. Such injuries in adults may be managed conservatively if the defect is less than half of the total penile skin. Complete denudation in the adult is managed by split-thickness skin grafting for optimum cosmetic and functional results[21,23,26]. Of three cases encountered by Gee and Ansell[24], one child with complete denudation had initial treatment by burial of the penis in a tunnel of scrotal skin; no follow-up was available on this patient. Use of a pedicled scrotal skin flap has recently been described for the reconstruction of penile shaft skin[27].

A rare consequence of excision of excess preputial skin is the so-called 'concealed penis'[23,25,28,29]. Kaplan[12] maintains that, although an excess of skin is removed, not enough inner preputial epithelium is excised. The new preputial orifice is,

0007-1323/93/101231-06 © 1993 Butterworth-Heinemann Ltd

therefore, distal to the glans, and as healing and fibrosis occur the penile shaft is forced into the suprapubic fat, with the resulting preputial ring at the level of the skin of the mons pubis. Other suggestions about the aetiology of this complication include a tendency of the penis to retract into the fatty mons pubis[29] and the possibility that the penile shaft is forced into a subcutaneous position by wound contraction[25]. Subsequent fibrosis of the circumcision wound leads to stenosis of the preputial orifice, which then traps the penile shaft subcutaneously[23,29]. Treatment of this condition is surgical correction. In the presence of phimosis, Kaplan[12] recommends a circumferential incision at the preputial ring to avoid the need for skin grafts to achieve coverage of the penile shaft. A vertical incision caudal to the circular scar was used by Kon[29] to expose the glans and penile shaft which was in a subcutaneous position, tightly adherent to the surrounding tissue. Nearly complete direct skin coverage was achieved, apart from a small ventral defect, which was covered by rotation of the scrotal skin. A vertical incision was used also by Byars and Trier[23], and, while Shulman *et al.*[25] did not state the incision employed, both required the use of skin grafts for coverage of the penile shaft. More recently, Radhakrishnan and Reyes[30] chose to use opposing U shaped incisions and so doing were able to obtain skin coverage with vascularized flaps; they contend that the functional and cosmetic results are superior to those of reconstruction with split-thickness grafts, which may result in comparatively inelastic skin on the penile shaft.

Many other forms of surgical mishap have been reported. Laceration to the penile skin and scrotum resulting in exposure of both testes as reported by Shulman *et al.*[25] was managed by primary suturing. Laceration of the penile shaft with resultant partial amputation has also been described[23]. Total ablation of the penis may occur as a result of diathermy injury[31] and loss of the penis from the use of a rubber band as a tourniquet has been reported[32]. Injury to the glans may result from inadequate separation of preputial adhesions. Glandular injury may be of varying severity and cases of complete surgical amputation of the glans have occurred[25]. McGowan[33] described a case in which inadvertent placement of scissors into the urethra while attempting a dorsal slit resulted in surgical bivalving of the glans.

Non-operative complications

Ruff *et al.*[34] described a case of myocardial injury following immediate postnatal circumcision. This was confirmed by a raised level of type MB creatine kinase and by left ventricular posterior wall hypokinesis on echocardiography. It was concluded that the exposure of the child to cold stress as a result of circumcision resulted in a persistent fetal circulation and hypothermia. The neonate had a satisfactory outcome on medical management. A case of recurrent pneumothorax following circumcision was reported by Auerbach and Scanlon[35] in a neonate. The circumcision was complicated by moderate bleeding and the baby's distress was sufficient to produce circumoral cyanosis and persistent tachycardia. It was concluded that crying, induced by the many dressing changes needed to obtain haemostasis, resulted in raised intrapulmonary pressure sufficient to rupture a weak site and cause pneumothorax. Although the child was managed successfully, this required a further hospital stay of 19 days.

Bleeding

Bleeding remains the commonest complication encountered during and after circumcision. Because varying criteria have been used when recording this complication and because of inadequacies in documentation, the reported incidence ranges from 0·1 to 35 per cent[3,12,24,25]. In the majority of cases bleeding is minor and all that is required to achieve haemostasis is gentle pressure on the area. Excessive bleeding may be due to anomalous vessels[25] or the presence of a bleeding disorder[24]. After 13 000 circumcisions reported in two large series, no patient required blood transfusion for bleeding[24,25]. In the event of a bleeding disorder, appropriate clotting factors may have to be administered[24]. The authors are not aware of any reported cases of exsanguination following circumcision.

In some instances the application of pressure alone is insufficient to control local haemorrhage and other methods of haemostasis must be employed. In the UK the commonest aid to haemostasis is electrosurgical diathermy for coagulating vessels. While in the majority of situations the judicious use of this device is safe and effective, the potential for damage exists if it is employed overzealously. When used in monopolar form, an electrical current flows from the indifferent electrode (plate) to the active electrode (forceps) and the tissue surrounding the forceps is heated, resulting in coagulation. However, this coagulation process may spread proximally in small vessels (a phenomenon commonly observed in everyday practice) and the extent of vessel coagulation may be far greater than anticipated or intended. It is predominantly for this reason that the present authors use only *bipolar* diathermy during circumcision. Although there are probably many undocumented cases of minor diathermy burns and sloughing of the affected penile skin, more severe injuries such as glans and major penile skin necrosis have been reported[22,27]. At its most severe, the use of diathermy may result in total ablation of the penis. Gearhart and Rock[31] described four such cases in which damage was so severe that plastic surgical reconstruction was deemed impossible. In all cases the children were managed by gender reassignment and feminizing genitoplasty.

If simple application of pressure is unsuccessful, a type of circumferential bandage may be applied to aid haemostasis. This appears to be popular among the practitioners of religious circumcision in Jewish communities. It may cause a degree of urethral obstruction which, in severe cases, leads to urinary retention[36] and may thus predispose to urinary tract infection[37]. Horowitz *et al.*[38] described such an event in which an 18-day-old infant presented shocked, dehydrated and with a hugely distended abdomen 2 days after circumcision. The tip of the penis, which was still covered by a circular bandage, appeared red and necrotic. After the bandage was released the child voided a large volume of urine and the abdominal distension disappeared. The cause of systemic upset was an *Escherichia coli* urinary tract infection and subsequent septicaemia. Frand *et al.*[39] described an infant about whom the parents were concerned because of bluish discoloration of the legs 1 day after circumcision; a circular bandage was seen around the penis. After this was removed a large volume of urine was voided and the lower-limb cyanosis rapidly disappeared. It is presumed that the distended bladder compresssed the iliac veins and so impeded venous return from the legs. Acute urinary retention may also be caused by the devices sometimes used for circumcision; in one case where the Plastibell device (Abbott Laboratories, Queenborough, UK) was employed, rupture of the bladder was a consequence of acute urinary retention[40]. As well as compressing the urethra, the blood flow to the distal penis and glans may also be compromised by the tourniquet action of a circumferential dressing, which in severe cases may result in necrosis of the distal penis and glans[41].

Pharmacological agents may also be used to stop minor troublesome bleeding and in this respect the application of 1:100 000 adrenaline solution is not uncommon. Although there is a slight danger from systemic absorption, at this low concentration complications are unlikely. If a more concentrated solution is used, however, there is greater systemic absorption with its attendant problems. Mor *et al.*[42] described four such cases in which a sponge-soaked solution of 1:1000 adrenaline had been applied to the circumcision wound and left in place for a few hours. All the children developed tachycardia and heart failure but were successfully managed with digoxin and diuretics. Denton *et al.*[43] reported a similar case of a neonate in whom 0·1 ml of 1:1000 adrenaline was sprayed on to the bleeding area of the frenulum after circumcision. The patient developed tachycardia, acrocyanosis and local pallor of the penis. After subcutaneous injection of phentolamine (an α-adrenergic receptor antagonist) at the base, shaft and corona of the penis, all penile pallor disappeared and the systemic signs abated.

As an alternative to diathermy, obvious bleeding vessels may be ligated with a fine suture. One of the commonest sites for persistent bleeding is at the frenulum, and in this area it is not uncommon to insert a haemostatic suture. However, because of the close proximity of the underlying urethra, it is easy for such a haemostatic stitch to be placed in the urethra itself. The result is the development of a urinary fistula[44,45]. Avoidance of this complication therefore depends on meticulous technique when suturing around the frenulum and in taking superficial tissue only in the stitch.

Sepsis

Infection occurs after circumcision in up to 10 per cent of patients[3,15]. In the majority of cases this is usually mild and manifested by local inflammatory changes, but occasionally there is ulceration and suppuration. Most infections are of little consequence and settle with local treatment. Occasionally, however, sepsis may have much more alarming consequences and may even cause death[46–48].

The perineal skin is heavily colonized by both normal skin saprophytes and by bowel flora, and it is surprising that significant septic complications do not occur more frequently. Woodside[49,50] reported a case of necrotizing fasciitis of the perineum after Plastibell circumcision in a neonate. The child was septicaemic and there was also bacterial contamination of the cerebrospinal fluid. Extensive surgical debridement of the perineum with multiple fasciotomy was necessary and parenteral antibiotics were administered. *Staphylococcus aureus*, *S. epidermidis*, diphtheroids, α-haemolytic streptococcus and *Clostridium perfringens* were cultured from the excised perineal and penile skin. The child survived and had a satisfactory cosmetic and functional result some years later.

Gangrene of the penis has also been reported following circumcision[51] and the scope of microbial contamination of the perineal skin can be further appreciated from the report of Sussman *et al.*[52] of two cases of Fournier's syndrome of the perineum and scrotum following the operation. Both patients survived after adequate antibiotic management, although extensive surgical debridement was necessary in one child. Annunziato and Goldblum[53] presented three cases of staphylococcal scalded skin syndrome all of which occurred after circumcision and, similarly, cases of impetigo have been documented[54]. In 1935, Gosden[47] reported a series of 23 boys from Cyprus circumcised by an unqualified practitioner in 13 of whom tetanus developed; five died. Diphtheria may develop in a circumcision wound[55] and infection with *Mycobacterium tuberculosis* has been documented[18]. The circumcision site has been observed to be the portal of entry in many other cases of sepsis, and Cleary and Kohl[56] reported a fatal case of septicaemia with group B β-haemolytic streptococcus in a 6-week-old child. Kirkpatrick and Eitzman[57] highlighted the significance and occurrence of septicaemia following circumcision with the Plastibell device. Metastatic infection from the circumcision site has been reported as a cause of neonatal meningitis in five children[58,59], three of whom were treated successfully with no long-term sequelae. However, one child subsequently developed cerebral palsy and one died. Osteomyelitis of the femur[25] and a fatal case of staphylococcal bronchopneumonia[60] have also been reported following circumcision. Recently, Crowley and Kesner[48] reported a 9 per cent mortality rate in a series of 45 consecutive admissions for septic complications following ritual circumcision in young adults. Septic embolization and polyarthritis were among the documented complications of septic circumcision in this series. Despite its apparently low incidence, sepsis following circumcision has the potential to cause significant morbidity and in some cases death.

Fistula

Urethrocutaneous fistula following circumcision may occur for a variety of reasons but, fortunately, the reported incidence of this complication is low. Perhaps the commonest cause is a poorly placed suture at the frenulum in an attempt to obtain haemostasis[44,45]. This results in strangulation and necrosis of part of the urethral wall, with resultant subglandular fistulation not dissimilar to glandular hypospadias. Fistulation may also occur as a result of sepsis[61] or unrecognized rare penile anomaly, such as megalourethra[62]. However, many other fistulas arise from using the Plastibell device or Gomco clamp[12,44]. Although the mechanism of injury is not clear it is probable that urethral injury results from crushing by the device. Most of these fistulas open on to the dorsum of the penis (but they may also open to the ventral surface), an anatomical arrangement not dissimilar to that seen in epispadias. Such a case was reported following surgical bivalving of the glans[33]. Although there are many approaches to the management of such a urethral fistula[63], appraisal of the techniques employed is beyond the scope of this review.

Meatal stenosis

Meatal stenosis is generally a direct consequence of circumcision that is seldom encountered in uncircumcised men; meatal calibre is known to be greater in uncircumcised individuals. The incidence of meatal ulceration following circumcision is from 8 to 20 per cent[14,46,64]. The aetiology is thought to be irritation of the external urethral meatus by ammoniacal substances present in wet sodden nappies. Such irritation is unlikely in the presence of a normal prepuce, which serves to protect the glans from these irritant substances[46]. In a prospective study of 140 consecutive neonatal circumcisions, Mackenzie[64] found a 20 per cent incidence of meatal ulceration within the first 2–3 weeks after circumcision. It is thought that meatal ulceration after circumcision is the initiating event in a vicious cycle of stenosis and ulceration, followed by more stenosis[64]. Meatal stenosis following circumcision has been advanced as a cause of recurrent pyelonephritis and obstructive uropathy, for which meatotomy is curative[64,65].

Miscellaneous complications

The glandular epithelium may be denuded by a less than gentle technique when separating the preputial adhesions and this may be exacerbated if the glans is held firmly by a gauze swab. The glans may then be more prone to local sepsis with the resulting formation of a scab. Fortunately, most settle spontaneously with attention to hygiene. A skin bridge may develop between the glans and the penile shaft. This may tether the erect penis so producing pain and deformity. The aetiology of this condition remains unknown, although injury to the glans at the time of circumcision or incomplete separation of the inner preputial skin have been advanced as possible factors[12,66]. Inclusion cysts following circumcision have been described. That reported by Shulman *et al.*[25] was found histologically to be an epidermal cyst. It is possible that cysts also arise as a result of peroperative implantation of smegma. The use of silica talc on surgical gloves has been associated with the formation of granulomas and such a lesion was described in a circumcision wound 15 years after the original surgical procedure[67]. Although penile lymphoedema following circumcision has been reported, there is a paucity of information regarding the aetiology and management of such a problem and accounts in the literature are anecdotal[12,25]. The degree of penile oedema may be greater with the Plastibell device[68]. Impotence has been observed following circumcision[69]. Palmer and Link[70] described two cases, both of which were associated with injection of 1 per cent lignocaine directly into the corpora after application of a rubber band at the base of the penis to act as a tourniquet. As 10–15 ml anaesthetic was used this perhaps resulted in a 50 per cent mixture of lignocaine and blood in direct contact with the vascular endothelium of the penis. It is postulated that this high concentration irreversibly damaged the endothelium of the corpora cavernosum with resulting impotence. Impotence followed partial amputation of the penis at circumcision, despite plastic surgical reconstruction, in a case reported by Hanash[71]. Hypospadias remains a contraindication to circumcision, as surgical reconstruction may require the use of all the available penile skin. However, circumcision in unrecognized hypospadias was performed in six children in one series and, in the same series, although hypospadias was recognized in two children, circumcision was performed anyway[24].

Carcinoma

Of 1103 patients with carcinoma of the penis reviewed by Wolbarst[72], none had been circumcised. It was therefore concluded that squamous carcinoma of the penis only ever occurs in uncircumcised men and that the circumcised state is protective against its development. However, squamous cell carcinoma of the circumcised penis has since been reported[73,74] and so the original contention of a protective effect of circumcision is not convincing. Indeed, when one compares the incidence of carcinoma of the penis in the USA (0–2·1 per 100 000) where most men have been circumcised at birth, with that in Denmark (1·1 per 100 000) and Japan (0·3 per 100 000), where circumcision is rarely performed, the original contention seems doubtful[5,75]. It is likely that several factors other than circumcision are implicated in the genesis of carcinoma of the penis.

Carcinoma of the penis following circumcision appears to have a different natural history from cancer in uncircumcised men. Whereas penile cancer in the uncircumcised tends to arise on the glans or prepuce, after circumcision the tumour is likely to develop in the surgical scar. Such tumours occur mostly on the penile shaft and tend to spread locally with distant metastasis as an infrequent or late occurrence[76]. Surgical excision is the treatment of choice, as neither radiotherapy nor chemotherapy appears to be effective[77]. Nearly all of these cases have been reported from Saudi Arabia, where there existed a radical form of circumcision that was practised by the tribes in the southern regions. The circumcision included excision of the skin in the suprapubic region with a longitudinal incision extending between the anterior superior iliac spines[78]. This practice is now prohibited.

Psychological complications

According to Freudian theory, by the fourth or fifth year of life the genital concentration of all sexual excitement is achieved and the boy's interest in the genitals attains a dominant significance, the phallic stage. Anna Freud[79] wrote:

> 'any surgical interference with the child's body may serve as a focal point for the activation, reactivation, grouping and rationalisation of ideas of being attacked, overwhelmed and (or) castrated'.

For a child at the phallic stage this fear that something might happen to his prized organ is called 'castration anxiety'. According to the psychoanalytical literature, operations performed on the penis, such as circumcision, may arouse such castration fears. In a study on circumcision and the problems of bisexuality, Nunberg[80] highlighted the point that injury to the penis may intimidate the child and impair his development to full virility. However, in the same paper he also proposed that circumcision may stimulate the masculine striving of the child by encouraging identification with the father. After a detailed prospective psychoanalytical study of 12 boys aged 4–7 years undergoing circumcision in Turkey, Cansever[81] found that following surgery there was a significant fall in intelligence quotient and that body image perception showed a tendency to contract. She concluded that:

> 'circumcision is perceived by the child as an aggressive attack upon his body, which damaged, mutilated, and in some cases totally destroyed him. The feeling of "I am now castrated" seems to prevail in the psychic world of the child. As a result he feels inadequate, helpless and functions less efficiently'.

Such psychological sequelae are not confined to the young child. Circumcision performed in the neonatal period is associated with marked behavioural changes[82,83] that may last up to 24 h; supporting this observation is the finding of a rise in both serum cortisol and cortisone levels after neonatal circumcision[84]. Circumcision in the neonate has been noted to increase both respiration and heart rate and is associated with a significant fall in transcutaneous oxygen tension[85]. Allied to this is a change in sleep pattern with prolonged non-rapid eye movement sleep. This change has been interpreted as 'being consistent with a theory of conservation–withdrawal to stressful stimulation'[86].

Circumcision can cause dysmorphophobia, and Walter and Streimer[87] reported a case of genital self-mutilation in a non-psychotic patient who attempted to reconstruct the foreskin himself. Two groups of men seeking restoration of the foreskin have been identified. First is a group of Jewish men who sought to disguise their religious identity during times of political crisis[88]. Second is a group of homosexuals whose circumcised status is associated with unwanted masculinity and anger over having no choice over their circumcision[89]. Genital self-mutilation by attempted circumcision has been reported after paternal death in two patients, both of whom demonstrated features of acute psychosis[90]. Schizophrenia following elective circumcision has also been reported[91].

In societies in which circumcision is intricately linked to tradition and culture, the uncircumcised individual is likely to be an outcast. This prejudice may be great enough for uncircumcised men not only to be ostracized by their peers but even to be attacked and beaten for their lack of conformity. Such beatings in men refusing to be circumcised have occurred in the Xhosa tribe of South Africa and, in one instance, the attack was violent enough to result in the development of 'crush syndrome'[48].

Sexual complications

Morgan[92] asserts that:

> 'penetration in the circumcised man has been compared to thrusting the foot into a sock held open at the top while, on the other hand, in the intact counterpart it has been likened to slipping the foot into a sock that has been previously rolled up'.

He also suggests that 'coitus without a foreskin is comparable to viewing a Renoir whilst colour blind'[93]. While it is impossible to reach an objective conclusion in this matter, some have risen to the challenge[94] and attempted to investigate the question. Although Harnes[95] concluded that 'the question remains unanswered' at the end of his study, the description of his methodology and findings makes for compulsive reading.

Conclusion

Many medical practitioners regard circumcision as a relatively minor procedure and, as such, it is likely to be delegated to a junior surgeon. It has already been observed that complication rate is directly related to operator inexperience[3]. Delegation to a junior colleague should occur only after the surgeon in training has been fully instructed in the operative procedure. Heightened awareness of the scope and potential for complications will of itself result in a reduced complication rate.

Despite the recommendation of the British Medical Association that circumcision should be performed only for medical reasons, controversy still exists over whether too many procedures are being carried out. It is hoped that a greater awareness of the incidence and scope of associated complications will encourage a more carefully considered decision on whether or not to circumcise.

Infrainguinal revascularization in the diabetic patient

P. A. Stonebridge and J. A. Murie

Vascular Surgery Unit, The Royal Infirmary, Edinburgh, UK
Correspondence to:
Mr P. A. Stonebridge, Department of Surgery, Ninewells Hospital, Dundee DD1 9SY, UK

This article reviews the epidemiological, anatomical and physiological background to infrainguinal arterial reconstruction in the diabetic patient. There is no firm evidence in the literature for the existence of a surgically significant occlusive 'small-vessel' disease in diabetic patients, either as an aetiological component in the pathogenesis of diabetic foot lesions or as a factor limiting the success of infrainguinal bypass grafting. Recent published results of infrainguinal vascular reconstruction in patients with diabetes are reviewed. These are encouraging; early aggressive treatment of lower-limb occlusive disease may be warranted in the diabetic patient.

Peripheral vascular, cerebrovascular and cardiovascular disease are more common in diabetics than in the normal population[1]. In the Framingham study[2] the age-adjusted incidence of intermittent claudication in diabetics was 12·6 per 1000 men and 8·4 per 1000 women; for non-diabetics the corresponding figures were 3·3 and 1·3 respectively[2]. A prospective study using Doppler ankle: brachial arterial pressure ratios has also shown that occult peripheral arterial disease is much more common in patients with type II non-insulin controlled diabetes than in unaffected controls; 22 per cent of diabetics had occult disease compared with only 3 per cent of controls[3]. Type II diabetes mellitus, which is present in 90 per cent of diabetics, carries a sevenfold to 20-fold increase in the incidence of lower-limb arterial occlusive disease[4]. The associated risk factors include raised plasma triglyceride levels, reduced plasma concentrations of high-density lipoproteins, hypertension and increased systolic blood pressure[3]. It is worth noting that the progression of atherosclerotic occlusive disease is relatively rapid in diabetics, which suggests that such patients with symptomatic disease might benefit from aggressive treatment at an early stage[5].

The amputation rate has been suggested as an 'outcome' performance indicator[6]. Between 35 and 45 per cent of all lower-limb amputations are carried out on diabetic patients, although not solely for peripheral vascular disease; standard of footcare[7], age and patient education[8] are the most important preventative factors[9,10]. In the USA, diabetic foot problems are the commonest indication for hospital admission in diabetics[11]. Patients with diabetes may account for 50–70 per cent of all non-traumatic amputations, a figure of some significance when it is appreciated that they make up only 2 per cent of the population[12–14]. These figures represent between 20 000 and 30 000 amputations[15] per year at an estimated cost[16] of US$ 200 million for 1980. The risk of amputation for a diabetic patient is between 15 and 70 times that for a non-diabetic[17,18]. Peripheral vascular disease is the costliest complication of diabetes mellitus in terms of inpatient bed usage[19,20] and in the USA accounts for 1·2 per cent of all hospital costs[21].

Anatomy and pathophysiology

In 1984, LoGerfo and Coffman[22] conducted a literature review of macrovascular and microvascular disease in diabetics. They highlighted the widespread misconception that patients with diabetes mellitus have arteriolar occlusive disease as an aetiological cause of lower-limb ischaemic lesions. This popular misconception stems from the 1959 report by Goldenberg and colleagues[23], who described the presence of periodic acid Schiff-positive material in the arterioles of diabetics; this was interpreted as a specific arteriolosclerosis associated with diabetes mellitus. It is important to recognize, however, that subsequent studies using the Goldenberg technique[24], arterial microcasting[25] down to 10 μm, plethysmographically derived pressure–flow relationships[26] and blood flow response to papaverine[27] have failed to confirm the presence of such lesions. As long ago as 1971, Barner and colleagues[27] concluded that vascular reactivity is not impaired and arterial reconstruction should not be withheld on the basis of arteriolar–capillary involvement in diabetics. Furthermore, the calcification of diabetic vessels is not associated with occlusive disease[28]. There is no evidence[29] for the 'endothelial proliferation' also reported by Goldenberg *et al.*[23]. Although abnormalities of microcirculatory physiology do exist, these are all of a non-occlusive nature. The capillary basement membrane is thicker in diabetics, with a reduced charge resulting from non-enzymatic glycosylation and decreased sulphonation of basement membrane components[30]. This may account for highly charged molecules such as albumin diffusing more readily across the capillary basement membrane[31]. The altered permeability may contribute to an altered cellular nutrition in the diabetic foot. Capillary basement membrane thickening in diabetics is actually associated with an increased luminal capillary diameter[32]. Nevertheless, there is no evidence of an altered diffusion of oxygen; indeed, it has been shown that the transcutaneous partial pressure of oxygen in the ulcerated diabetic foot is frequently raised above normal[33]. The situation is complex in that capillary pressure within the diabetic foot is abnormally high[34], but laser Doppler ultrasonographic studies have shown a reduction of cutaneous microvascular blood flow, volume and erythrocyte velocity, particularly in the lower limb[35], suggesting that there is an impairment of skin blood flow. There is no distal predominance of this abnormality, which suggests that its cause is not neuropathic. The explanation for these changes may be deep cutaneous capillary loss, increased capillary resistance or selective loss of arteriovenous shunts.

The distribution of macrovascular occlusive disease in diabetic patients differs from that in non-diabetics. Conrad[25] used amputation specimens to demonstrate that occlusive atherosclerosis in diabetes tends to involve the infrageniculate arteries between the knee and ankle, sparing the foot. Strandness *et al.*[24] confirmed this as the major site of atherosclerosis and also showed that the foot vessels of diabetics are not dramatically different from those of non-diabetics in terms of sparing by atherosclerosis. Strandness also found that the dorsalis pedis artery was spared in about 70 per cent of both diabetic and non-diabetic individuals; a more recent angiographic study confirmed this observation[36].

Evaluation

Diabetics with peripheral vascular disease are at greater risk of the more severe manifestations of ischaemia, such as rest pain, ulceration and gangrene, than non-diabetics[37,38]. A principal reason for this is that the lower limb of the patient with diabetes is often affected not only by vascular disease but also by peripheral neuropathy. The overall effect is that a high arterial perfusion pressure is required to prevent ulceration and small areas of gangrene; these lesions may occur in the presence of relatively mild ischaemia in the diabetic patient. While this should be kept in mind when evaluating the diabetic, the single most important step in assessment of infrainguinal vascular disease is the same as in the non-diabetic patient, namely the examination of peripheral pulses. Although diabetic individuals have a greater propensity to develop occlusive tibial artery disease, the superficial femoral artery is still the commonest site of arterial occlusion[39].

Non-invasive investigation using a hand-held Doppler ultrasonographic probe to detect opening pressure is affected by the presence of medial calcinosis in the arteries of patients with diabetes. This may raise the luminal opening pressure by about 25 mmHg over that found in the non-diabetic patient with the same infrainguinal arterial pressure; in some diabetics it may be impossible to obliterate the Doppler signal[40,41]. The critical level of pressure associated with healing of foot ulceration in diabetics is higher than in non-diabetics[42]; this is possibly the product of this occlusion artefact. The difficulty caused by the unobliterable signal may be overcome by using toe digital artery opening pressure[43]. Measurement of the transcutaneous partial pressure of oxygen is not reliable in diabetics with ulceration; such patients frequently have a higher oxygen tension than non-diabetics with ulcers, and amputation wounds and ulcers may fail to heal at levels of oxygenation that would be adequate in non-diabetic patients[33]. A more recent report claimed a greater predictive value for transcutaneous partial oxygen pressure measurement if both supine and elevated readings are made[44]. Although clinical examination is important, it has been recommended that in a small number of cases angiography may still be appropriate despite palpable foot pulses[45].

Modern digital subtraction angiography (DSA) allows good imaging of small-bore distal vessels, which standard angiography may fail to outline[46,47]. Concern has been raised about contrast agent-induced renal failure in the diabetic patient, but there appears to be no increased incidence of such renal failure in diabetics with normal renal function[48]. However, the risk of developing renal failure in the presence of renal insufficiency has been reported to be as high as 41 per cent[49]; it is important to maintain adequate renal output before, during and after angiography by the use of diuretics[50], hydration or both[51]. The nephrotoxicity of contrast agent is related to its hypertonicity following dissociation into two ions[52], possibly due to morphological changes in the red blood cells causing microvascular obstruction[53], and a direct toxic effect on the renal cell[54]. Other possible causes of nephrotoxicity are related to protein tubular obstruction[55], urate nephropathy secondary to a uricosuric effect of contrast agent[56], and antibodies to contrast agent causing antigen–antibody complex deposition or renal cell cross-reactivity[57]. The nephrotoxic effect appears to be dose related (measured in grams of iodine), with 80–90 g iodine being the approximate dose at which the risk of renal failure increases significantly[58]. The development of non-ionic contrast agents, which do not dissociate, has reduced the incidence of renal failure following angiography[59,60]. DSA, in which computer enhancement of images allows the use of smaller doses of contrast agent, has been heralded as a better method of visualizing the distal vessels of the leg[61,62], although some have expressed concern about the clarity of the final image[63].

Clinical results

It is widely believed that operative risk is greater in diabetic than non-diabetic patients undergoing infrainguinal revascularization. Diabetics have a greater incidence of coronary artery disease, hypertension and renal insufficiency. Nevertheless, the incidences of previous myocardial infarction and cerebrovascular accident have been shown to be virtually the same in the diabetic and non-diabetic populations at the time of vascular reconstruction; approximately 40 per cent of patients have had a myocardial infarction and 12 per cent a stroke[38,64].

In the 1970s it was suggested that the diabetic with limb-threatening ischaemia was not a good candidate for revascularization[65,66]. What of more recent results specifically related to vascular reconstruction? Comparison of 5-year patency rates for infrainguinal bypass grafting in a single institution showed a favourable result in the diabetic population; a patency rate of 62 per cent was achieved in 95 diabetics compared with 52 per cent in 72 non-diabetics, with good rates of utilization of vein, 94 and 76 per cent respectively[64]. A further comparison of 75 diabetic and 75 non-diabetic patients undergoing infrainguinal bypass (approximately 80 per cent to below the knee joint in both groups but with significantly more to tibial and pedal vessels in the diabetics) demonstrated 1- and 4-year patency rates of 95 and 89 per cent respectively in the diabetic group compared with 85 and 80 per cent in the non-diabetics[67]. The largest study available, comparing 387 diabetics and 294 non-diabetics receiving tibial artery bypass grafts, showed 1- and 5-year patency rates of 91 and 74 per cent in patients with diabetes, compared with 90 and 76 per cent in those without[68]. These reports are summarized in *Table 1*. The most recent study dealing with this type of comparison was reported in 1992; it did not give patency data for individual groups but reported an overall 3-year primary patency rate of 58 per cent, stating that no statistically significant difference existed between results for insulin-controlled diabetics, non-insulin controlled diabetics and non-diabetics[38]. It is also worth recording the results of an aggressive revascularization policy towards juvenile-onset diabetes mellitus (type I) from the New England Deaconess Hospital, Boston; a 2-year primary vein graft patency rate of 83 per cent was achieved, with 16 per cent of the study group dying within this period[69].

Infrainguinal bypass, the origin of which is distal to the common femoral artery, has been regarded by many as only a compromise procedure, for use when insufficient length of vein is available[70,71]. It is important to appreciate, however, that the distribution of atheromatous disease in patients with diabetes mellitus is typically tibioperoneal. It is not uncommon to find ischaemic foot lesions in the presence of a palpable

popliteal pulse and the popliteal artery may frequently provide a suitable site of origin for a bypass graft. Diabetics may have both spared and stable inflow and outflow tracts, which may optimize the results of popliteal–distal vessel bypass. In 1981, Veith and colleagues[72] reported acceptable results following use of the distal superficial femoral or popliteal artery as an inflow site. Only 3 per cent (one graft) of their series possibly occluded because of progression of more proximal disease. Stonebridge and colleagues[73], in a series of 124 popliteal–distal bypass grafts, reported 1- and 3-year primary patency rates of 89 and 85 per cent, with a perioperative mortality rate of 0·8 per cent. Similar results have been reported by others[74–79] (*Table 2*). A significant advantage of such a manoeuvre is that the graft length is shortened. Ascer and colleagues[80] showed in a non-randomized retrospective study that there is a statistically significant advantage in terms of patency rate for short over long vein grafts, especially in the presence of poor run-off. Shorter grafts also facilitate use of alternative conduits such as arm vein and short saphenous vein[81].

Budd and colleagues[82] on simple analysis suggested that diabetes was a significant adverse risk factor for graft patency; however, when proportional hazards analysis was performed diabetes no longer appeared significant. In contrast, Rutherford and colleagues[83], in an analysis of factors affecting graft patency, showed a significant advantage for diabetic patients.

How far distally can one insert a bypass graft and hope for success? Pomposelli and colleagues[84], in a series of patients containing 94 per cent with diabetes, reported 97 bypasses to the dorsalis pedis artery, using the femoral artery as the graft origin in 50 per cent and the popliteal artery in the remainder. There was an 18-month graft patency rate of 82 per cent; limb salvage and patient survival rates at 18 months were 87 and 80 per cent respectively. Twelve dorsalis pedis arteries in this series were explored despite not being imaged on preoperative DSA; six were found to be satisfactory for the insertion of a bypass graft. Harrington and colleagues[85] also reported a series of patients with bypass to the dorsalis pedis artery that included 78 per cent diabetics. Some 73 bypasses were carried out with a 2-year graft patency rate of 59 per cent. Failure was attributed to poor vein quality, continuing foot infection and skin incision necrosis. Andros and colleagues[86] reported the results of bypass grafts to 20 lateral plantar arteries; there were 16 diabetic patients in the series. Ten bypasses originated from the popliteal artery, four from the common femoral artery and six from previous grafts. The patency rates documented only at 1 and 3 months were 85 and 73 per cent respectively. A summary of the results of infrainguinal bypass in diabetic patients over the past 5 years is given in *Table 3*. This shows a range for 1- and 3-year patency rates of 71–94 per cent and 56–88 per cent respectively.

Table 2 *Primary patency rates of infrainguinal bypass grafts originating from the popliteal artery*

The problem of calcification in the arteries of diabetic patients has already been mentioned. Medial calcification, shown radiologically, occurs twice as commonly in diabetics as in non-diabetics[23] and such calcification might be thought to be detrimental to vascular reconstruction. The question has, however, rarely been addressed. Ascer and colleagues[87] described no statistically significant difference between the long-term patency rates of grafts to circumferentially calcified ($n = 36$), partially calcified ($n = 203$) and non-calcified ($n = 116$) tibial vessels; the respective 3-year patency rates were 47, 58 and 45 per cent. They concluded that 'arterial calcification is an invalid predictor of failure in small vessel bypasses'. This view was supported by results from a smaller series of patients with calcified distal arteries, for whom the 3-year graft patency rate did not differ from that after bypass to non-calcified vessels[88].

The other main local problem associated with diabetic peripheral vascular disease is the concurrent presence of foot sepsis and ischaemia. While such sepsis may delay surgery because of the need for local debridement or amputation (although certain centres report no difference in this respect between diabetic and non-diabetic patients[64]) and may increase the length of hospital stay after operation, the 3-year patency rate for bypass grafts in such situations may be as high as 92 per cent, with a corresponding 96 per cent limb salvage rate[89]. Rubin and colleagues[90] compared reconstruction to the tibial arteries in the presence and absence of pedal sepsis. Not only was there a greater proportion of diabetics than non-diabetics in the group with sepsis, 74 *versus* 44 per cent, there was also a greater proportion of smokers, 85 *versus* 62 per cent. Graft patency data were not recorded but limb salvage rates were not statistically different 3 years after operation: 68 per cent for patients with foot sepsis at the time of surgery *versus* 74 per cent for those without.

In summary, the literature contains few data to suggest that successful infrainguinal bypass is less likely in diabetics than in non-diabetics; rather, the opposite may be true. Several studies have also indicated that early aggressive surgical treatment of lower-limb occlusive arterial disease may be warranted in the diabetic patient. Indeed, it has been claimed that distal arterial reconstruction is a principal factor in reducing the frequency of amputation for ischaemia in diabetic patients[91]. The reported series of such operations from specialist vascular centres describe good results with long-term durability.

Table 3 *Primary patency rates of infrainguinal bypass grafting in populations containing a high percentage of diabetic patients*

Reference	Year	No.	Diabetics (%)	Patency rate (%) 1 year	Patency rate (%) 3 years	Patency rate (%) 5 years	Comments

Paper accepted 7 June 1993

Surgical Research Society

The following six papers were presented at the 77th meeting of the Surgical Research Society, with Professor L. E. Hughes in the chair. The meeting was held on 7–8 January 1993 at the Charing Cross and Westminster Medical School, London.

Br. J. Surg. 1993, Vol. 80, October, 1242–1245

Smoking impairs endothelium-dependent relaxation of saphenous vein

Samples of proximal saphenous vein were obtained from heavy smokers and non-smokers: 28 were obtained at varicose vein surgery and eight at infrainguinal bypass surgery. The veins were prepared for histological examination and for mounting in an organ bath to measure changes in isometric tension. Vein rings from both smokers and non-smokers responded equally to sodium nitroprusside, a reagent that acts directly on smooth muscle cells, undergoing 90–100 per cent relaxation. The mean(s.e.m.) maximum relaxation in response to bradykinin of rings obtained at varicose vein surgery was 50·0(5·3) per cent in non-smokers compared with only 31·6(2·2) per cent in smokers (P = 0·03). Similarly, in specimens obtained at bypass surgery the mean(s.e.m.) maximum relaxation in smokers was only 25·1(6·3) per cent compared with 48·4(4·1) per cent in smokers (P = 0·04). Relaxation in response to the bradykinin stimulus was abolished in the presence of L-nitroarginine methyl ester, a specific inhibitor of the synthesis of endothelium-derived relaxing factor (EDRF). Preincubation of the vein rings with L-arginine, the precursor of EDRF, did not increase the vasorelaxation in smokers. The mean(s.e.m.) maximum relaxation in response to the calcium ionophore A23187 was 53·5(3·8) per cent in non-smokers compared with only 27·0(4·9) per cent in smokers (P = 0·01). The results indicate that heavy smokers have impaired release of EDRF in response to both bradykinin and calcium ionophore. This impairment may increase vasomotor tone, platelet aggregation and smooth muscle proliferation, thereby resulting in an increased risk of graft occlusion.

Mr D. J. Higman

Saphenous vein is the optimum conduit for infrainguinal bypass, especially where the graft crosses the knee[1–3]. Occlusion of vein grafts is a major problem in vascular surgery and may lead to limb loss. Most vein graft occlusions occur within 6–12 months after bypass surgery. A major cause of early failure is the development of intrinsic lesions, which lead to narrowing of the lumen and graft thrombosis[4,5]. Other factors that contribute to graft occlusion include continuation of smoking after bypass surgery and raised levels of plasma fibrinogen[6]. Smoking is considered to damage the endothelium, but no particular studies have been carried out on the effect of smoking on the endothelium of saphenous vein. Vascular endothelium produces two endogenous vasodilators, prostacyclin and endothelium-derived relaxing factor (EDRF). EDRF is now known to be nitric oxide. These two vasodilators also act synergistically to inhibit platelet aggregation and adhesion, processes that could directly promote thrombosis. Smoking has been demonstrated to reduce the production of prostacyclin by cultured vascular endothelial cells[7]. Recently it has been demonstrated that endothelium-dependent regulation of arterial tone is impaired in smokers[8]. In this study, endothelium-dependent relaxation of saphenous vein, which is also impaired in smokers, is reported.

Patients and methods

Segments of proximal long saphenous vein were obtained with minimal trauma from two groups of patients, those undergoing ligation and excision of the long saphenous vein for the correction of varicose veins (28 patients) and those undergoing distal revascularization for critical ischaemia (eight). Preoperative duplex ultrasonography demonstrated competence of the long saphenous system in patients receiving bypass. Smokers were defined as current smokers with at least a 10 pack-year history of smoking. In the varicose vein group, non-smokers were patients who had never smoked; in the vein bypass group, non-smokers were those who had not smoked for at least 5 years. Serum samples were obtained at the time of surgery for estimation of cotinine, the principal stable metabolite of nicotine; cotinine levels >200 nmol/l were considered indicative of current smoking. Patients with diabetes, those receiving antihypertensive or nitrate therapy, and those who had previously had venous thrombosis or venous surgery were excluded from the study. The demographic details of the patients are shown in *Table 1*.

Cotinine range (nmol/l)	36–106	38–82

Materials

L-arginine, bradykinin acetate, L-nitroarginine methyl ester (L-NAME), calcium ionophore A23187, sodium nitroprusside, indomethacin and L-phenylephrine were all obtained from Sigma Chemicals, St Louis, Missouri, USA. Krebs' Ringer solution contained 118·4 mmol/l NaCl, 4·7 mmol/l KCl, 2·5 mmol/l $CaCl_2$, 1·2 mmol/l $MgSO_4 \cdot 7H_2O$, 24·9 mmol/l $NaHCO_3$, 1·2 mmol/l KH_2PO_4, 11·1 mmol/l glucose and 10 μmol/l indomethacin.

Histological examination

A segment of saphenous vein adjacent to that used for organ-bath studies was fixed in either 10 per cent buffered formalin for light microscopy or in 1 per cent glutaraldehyde for scanning electron microscopy, which was used to confirm that the endothelial cell layer was intact.

Organ-bath studies

The segment of proximal saphenous vein was excised and placed immediately into modified Krebs' solution at 4°C and transported to the laboratory. Excess fat and connective tissue were carefully dissected from the 2-cm segment, and 5-mm vein rings cut and suspended between metal stirrups in the chamber of an organ bath containing 10 ml Krebs' Ringer buffer at 37°C, oxygenated with 95 per cent oxygen mixed with 5 per cent carbon dioxide. The upper stirrup was connected by surgical silk to an isometric type D transducer (Bioscience, Washington, Sheerness, UK) and the lower stirrup to a glass tissue holder. The vein ring was allowed to equilibrate for 60 min, during which time the chamber solution was changed every 15 min. Vein rings were stretched at 0·5-g intervals and exposed to phenylephrine (0·3 μmol/l) at each level of stretch until the optimum length–tension relationship was obtained, usually 2–3 g. After a further 30 min equilibration, a dose–response curve to phenylephrine (10^{-9} to 10^{-4} mol/l) was obtained. The vein ring was then washed thoroughly with Krebs' Ringer solution and allowed to equilibrate for a further 30 min before agonist-induced relaxation. For this, vein rings were exposed to a submaximal dose of phenylephrine and accumulative doses of bradykinin (10^{-9} to 10^{-5} mol/l) or calcium ionophore (10^{-9} to 10^{-5} mol/l), which were added at intervals of 2 min or until a stable response was observed. After each relaxation dose–response curve, the vein rings were again washed thoroughly with Krebs' Ringer solution and a further 30 min equilibration allowed before a new dose–response curve was estimated. For some experiments, vein rings were preincubated with L-NAME (0·1 mmol/l) for 30 min before a dose–response curve was performed. In other circumstances, vein rings from smokers were preincubated with 3 mmol/l L-arginine for 30 min before the dose–response curve was effected.

Results

Serum cotinine levels for the patients are shown in *Table 1*. All those considered as non-smokers had cotinine levels <200 nmol/l and all smokers had levels in excess of this value. Light microscopic examination of vein segments did not reveal gross intimal thickening or damage in any of the specimens used in organ-bath studies. Scanning electron microscopy demonstrated that the endothelium was well preserved with no significant areas of endothelial damage or denudation in the vein specimens (*Figure 1*).

The logarithm of the concentration of phenylephrine required to produce 50 per cent contraction was similar for vein rings from smokers and non-smokers. Sodium nitroprusside bypasses the endothelium and acts on the smooth muscle to produce direct relaxation of vein rings. The mean(s.e.m.) maximum relaxation in response to 10 μmol/l nitroprusside was similar in both groups, 96·4(3·1) per cent in non-smokers (17 patients) and 93·8(5·3) per cent in smokers (19).

The dose–response curves for relaxation in response to bradykinin of the specimens obtained at varicose vein surgery are shown in *Figure 2*. The mean(s.e.m.) maximum relaxation in non-smokers (seven patients) was 50·0(5·3) per cent and that in smokers (nine) 31·6(2·2) per cent ($P = 0{\cdot}03$, Mann–Whitney *U* test). The logarithm of the concentration required to produce 50 per cent of the maximum relaxation (EC_{50}) did not differ significantly between non-smokers and smokers. The dose–response curves for bradykinin-induced relaxation of vein rings obtained at bypass surgery are shown separately in *Figure 3*. Again, the mean(s.e.m.) maximum relaxation in non-smokers (four patients) was significantly greater than that in smokers, 48·4(4·1) and 25·1(6·3) per cent respectively ($P = 0{\cdot}04$, Mann–Whitney *U* test). The EC_{50} for bradykinin was similar for smokers and non-smokers. The shapes of the dose–response curves for the vein rings obtained at bypass surgery are different from those for rings obtained at varicose vein surgery. The

Preincubation of vein rings from smokers with 3 mmol/l* L*-arginine* (●; n = *4*) *did not increase the maximum relaxation to bradykinin*

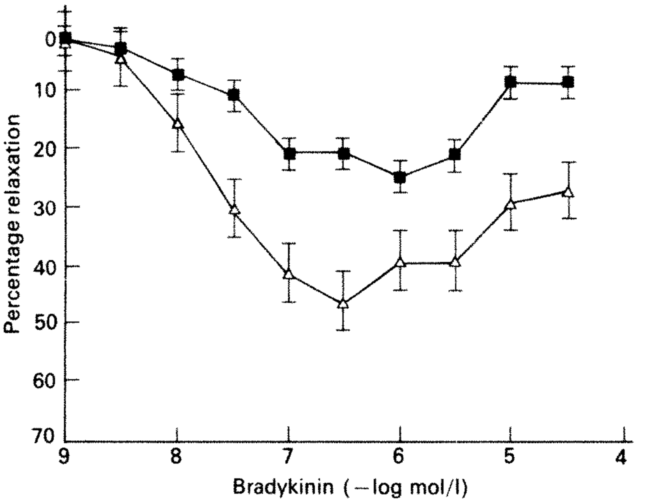

Figure 3 *Cumulative dose–response curves to bradykinin for vein rings obtained at bypass surgery. Relaxation is expressed as the percentage decrease in tension of the contraction induced by phenylephrine. Values are mean(s.e.m.). The mean maximum relaxation in non-smokers* (△; n = *4*) *was significantly greater than that in smokers* (■; n = *4*) (P = *0·04, Mann–Whitney* U *test*)

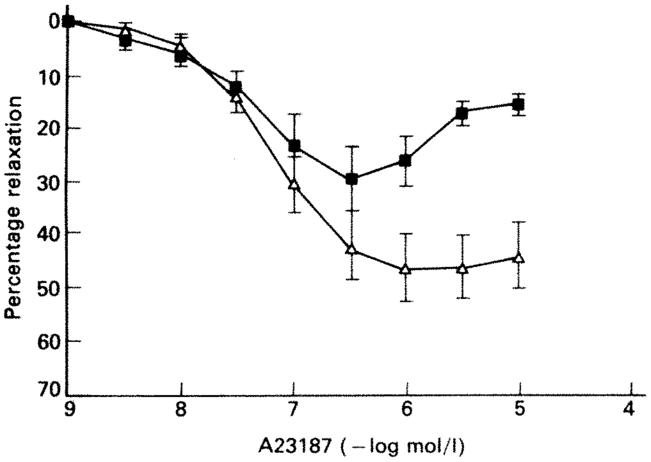

Figure 4 *Cumulative dose–response curves to calcium ionophore A23187 for vein rings obtained at varicose vein surgery. Relaxation is expressed as the percentage decrease in tension of the contraction induced by phenylephrine. Values are mean(s.e.m.). The mean maximum relaxation in non-smokers* (△; n = *6*) *was significantly greater than that of smokers* (■; n = *6*) (P = *0·01, Mann–Whitney* U *test*)

mean(s.e.m.) EC_{50} for bradykinin for bypass veins was significantly lower than that for vein rings obtained at varicose vein surgery: 0·25(0·02) × 10^{-7} mol/l for bypass vein and 1·50(0·02) × 10^{-7} mol/l for varicose vein ($P = 0·03$, Mann–Whitney *U* test). Preincubation of the vein rings from both non-smokers and smokers with L-NAME abolished the relaxation to bradykinin, confirming that the vasorelaxation was being mediated by nitric oxide (*Figure 2*). Preincubation of vein rings from smokers with 3 mmol/l L-arginine did not increase the maximum response to bradykinin (*Figure 2*).

Further experiments investigated the response of vein rings obtained at varicose vein surgery to the calcium ionophore A23187. For rings obtained at varicose vein surgery the mean(s.e.m.) maximum relaxation in response to A23187 was 53·5(3·8) per cent in non-smokers compared with only 27·0(4·9) per cent in smokers ($P = 0·01$, Mann–Whitney *U* test) (*Figure 4*). Similarly, for veins harvested at bypass surgery, the results in response to A23187 were closely similar to those for bradykinin, with increased maximum relaxation in non-smokers compared with smokers (data not shown).

Discussion

The obligatory role of the endothelium in controlling vasomotor tone was first described by Furchgott and Zawadski[9] in 1980. Several years later it was demonstrated that endothelial cells synthesize and secrete EDRF, further characterized as nitric oxide[10,11]. Other important effects of nitric oxide are inhibition of platelet aggregation and adhesion, and reduction of the proliferation of vascular smooth muscle cells in culture[12,13]. Recently, a non-invasive method has been described[8] for the investigation of arterial endothelial cell dysfunction *in vivo*: this involves monitoring the diameters of the brachial and superficial femoral arteries in response to changes in arterial blood flow. The endothelium-dependent relaxation of superficial femoral artery was reduced in smokers, whereas endothelium-independent relaxation, by glyceryl trinitrate, was unaffected[8].

Basal release of nitric oxide is higher in arteries than in veins[14]. Nevertheless, it has been considered[15] that nitric oxide release could have an important role in maintaining the patency of vein bypass grafts. The early success of vein bypass grafting may be short lived since vein graft stenosis and occlusion are major clinical problems. Most vein graft stenoses and occlusions occur within the first year after bypass surgery and it has been advocated[16,17] that all vein grafts should remain under continuous surveillance during this time. The aetiology of vein graft failure has been attributed to the formation of strictures, intimal hyperplasia, thrombosis and progression of distal disease. The risk of vein graft failure is increased in smokers[6]. Some of this increased risk might result from impaired release of nitric oxide from the endothelium of vein grafts, both at the time of grafting and later as the grafts adapt to the arterial circulation.

The similar vasorelaxation of saphenous vein rings of smokers and non-smokers to sodium nitroprusside indicates that smoking does not directly damage the vasomotor responses of the venous smooth muscle cells. This is in agreement with the findings of Celermajer *et al.*[8] for the arterial circulation. Bradykinin effects the synthesis and release of nitric oxide (EDRF) by stimulation of a receptor on the surface of the endothelial cell. The calcium ionophore A23187 bypasses membrane receptors and acts directly to affect intracellular calcium levels and stimulate the synthesis and release of nitric oxide. Both these agonists produced much greater relaxation in the vein rings of non-smokers compared with those of smokers, and relaxation of the vein rings of smokers was not increased by preincubation with L-arginine. The relaxations were blocked by L-NAME, a specific inhibitor of nitric oxide synthesis; all experiments were performed in the presence of indomethacin to inhibit vasoactive prostanoid formation. Therefore, the reduced relaxation in smokers appears to be dependent on nitric oxide, but specifically was not attributable to either a membrane receptor defect or to the depletion of L-arginine, the precursor of nitric oxide.

Most of the studies were performed using proximal saphenous vein harvested at varicose vein surgery. Even in patients with varicose veins, the proximal saphenous vein was minimally dilated and the intima histologically normal. These patients were significantly younger than those undergoing bypass surgery, and the smokers had shorter smoking histories. Similar effects of smoking on bradykinin-induced relaxation were seen in both veins obtained at varicose vein surgery and those from bypass grafting. However, there were differences in the response of the older bypass veins, including a lower EC_{50}, even though the mean maximum relaxation of non-smokers was similar in both groups, as was that of smokers. The similarities provide reassurance that the results of endothelial function in the proximal saphenous vein harvested at varicose vein surgery are also applicable to bypass veins. The patient exclusion criteria strictly limited the number of bypass veins available for investigation. Nevertheless, even with only four patients in each group, there was a clear difference between smokers and non-smokers.

From the present studies it can be concluded that endothelium-dependent relaxation of vein and release of nitric oxide from vein are reduced in smokers. With the knowledge that endothelium-dependent relaxation of the arterial circulation is also impaired in smokers, the reduced vasorelaxation of saphenous vein in smokers is likely to be maintained as the vein graft matures[8]. Since nitric oxide has important influences on two other processes associated with graft failure, platelet aggregation and smooth muscle cell proliferation, the impaired release of nitric oxide in smokers' veins and vein grafts could provide the common underlying mechanism for the increased risk of graft failure in smokers.

Type III collagen contributes to the tensile strength of the aortic wall, and mutations in the type III collagen gene have been suggested as the basis for the familial tendency to abdominal aortic aneurysm (AAA). Variation in this gene was investigated in 153 patients with AAA, 87 with aortoiliac stenosis and 98 age-matched controls. The rare mutation at amino acid 619 of Gly → Arg, previously associated with AAA in a single family, was not found in any of the patients with aneurysm. For the Ala → Thr variation at amino acid 531, the frequency of the threonine allele was 0·25 in patients with AAA and stenosis, compared with 0·35 in controls. The frequency of the rare allele in the region 3′ to the gene demonstrated by Ava II digestion (0·27 in the general population) was found to be 0·29 in the AAA group and 0·19 in the stenosis group (P = 0·023). In the AAA group the presence of the Ava II rare allele was associated with a significant increase in aneurysm diameter (P = 0·044). Non-invasive assessment of aortic distensibility was available in 25 patients: those carrying the Ava II rare allele had less distensible aortas than those not carrying this allele (median pressure–strain elastic modulus 42·0 and 23·9 N/cm^2 respectively, P = 0·008). Variation in the type III collagen gene may influence the mechanical properties of the ageing aorta and hence its susceptibility to disease and dilatation. In contrast, there is no evidence for a single common founder mutation in type III collagen predisposing to AAA.

Atherosclerosis diffusely affects many arteries. In smokers the disease appears to have a predilection for the abdominal aorta[1]. Other considerations, including flow, mechanical forces and the microanatomy of the aortic wall, are likely to dictate whether a haemodynamically significant stenotic lesion develops in the aortoiliac segment. Similar considerations are likely to influence the development of abdominal aortic aneurysm (AAA). However, there also is strong familial predisposition to AAA, indicating a genetic component[2–4].

Aortic fragility and aortic rupture have been associated with mutations in two of the connective tissue components of the aortic wall: fibrillin in Marfan's syndrome and type III collagen in Ehlers–Danlos type IV disease[5,6]. Also a mutation, Gly → Arg, at position 619 in type III collagen has been associated with AAA in a single family in the USA[7]. Collagen provides great tensile strength. However, in the normal aorta elastin is considered to be a more important load-bearing component[8]. As the aorta ages, stiffens and becomes susceptible to degenerative change, the load-bearing components alter such that collagen becomes more important[8,9]. Although type III collagen comprises only one-third of the aortic media collagen (the remainder being principally type I), it is the more extensile collagen and is, therefore, important in resisting pulse pressure.

In this paper evidence is presented to suggest that variation in the type III collagen gene may influence both the development of disease in the abdominal aorta and, more particularly, the extent of aneurysmal dilatation; it is not confirmed that mutations in type III collagen are a common genetic cause of AAA.

Patients and methods

Patients were recruited consecutively from the Charing Cross Hospital arterial clinic and included 153 with AAA, 87 with haemodynamically significant aortoiliac stenosis resulting in intermittent claudication or Leriche's syndrome, and 98 control subjects with atherosclerotic disease of the carotid artery or peripheral arteries supplying the lower limb (femoropopliteal disease without a significant aortoiliac component). The demographic features of these three groups are given in *Table 1*. The maximum anteroposterior external aortic diameter of all patients was measured using B-mode ultrasonography. Aortoiliac stenosis was assessed by angiography, colour-flow Doppler ultrasonography (Acuson 128; Acuson, Mountain View, California, USA) and segmental pressure decrease in the leg arteries.

For each patient a blood sample was obtained and used for the measurement of cotinine and cholesterol levels, determination of haptoglobin phenotype and for the isolation of genomic DNA. The genomic DNA was assessed for the presence of two polymorphic variations in or close to the type III collagen gene: the variable Ava II site 3′ to the gene, determined by Southern blotting, and the variable Alu I site, associated with an Ala → Thr variation at position 531 of the protein, using a polymerase chain reaction[10,11]. The presence of a Gly → Arg mutation at amino acid 619 was investigated as described previously[7].

In 25 consecutive patients presenting for elective repair of AAA between March and September 1989, the pressure–strain elastic modulus of the dilated abdominal aorta was investigated non-invasively using M-mode ultrasonography[9].

For statistical analysis, the Mann–Whitney *U* test was used to compare non-parametrically distributed variables, the χ^2 test to compare gene allele frequencies and analysis of variance to associate aneurysm diameter with other variables.

Results

The details of the three groups of patients given in *Table 1* include information about diabetes and ischaemic heart disease, angina or previous myocardial infarction, blood pressure and cholesterol measurements. The patients with AAA were significantly older, taller, had a lower incidence of diabetes and were disproportionately male compared with the other two

0007-1323/93/101246-03 © 1993 Butterworth-Heinemann Ltd

groups. The ethnic distribution among the three groups was similar.

The frequency of the allele coding for threonine at position 531 of type III collagen (Alu I polymorphism) was the same, 0·253, in patients with AAA and in those with aortoiliac stenosis. In controls the allele coding for Thr-531 was more common, 0·352 (*Table 2*); the difference between the AAA group and controls was significant (P = 0·040). Polymorphic variation at the Ava II site was determined only in the AAA and stenosis groups: information concerning the frequency of this polymorphism in the general population has been reported previously, with a frequency of 0·27 for the rare allele[10]. The frequency of the rare Ava II allele in the AAA group was 0·288, similar to that in the normal population, but its frequency in the stenosis group was significantly lower, 0·186 (P = 0·023). The presence of a Gly → Arg mutation at amino acid 619 of type III collagen was not detected in any patient (*Table 2*).

In the AAA group there was no association between aneurysm diameter and age, blood pressure, cholesterol level or haptoglobin phenotype. Women had smaller aneurysms than men (median diameter 5·5 *versus* 7·0 cm, P = 0·011). There was a significant association of aneurysm diameter with the Ava II genotype. Patients homozygous for the common allele (1–1) had the lowest median aortic diameter and those homozygous for the rare allele (2–2) the highest, with heterozygotes (1–2) being intermediate (*Figure 1*). Possession of the rare allele (1–2 or 2–2) was associated with an increased aneurysm diameter (P = 0·044). There was no association of aneurysm diameter with the Ala → Thr (Alu I) polymorphism or haptoglobin phenotype. The presence of the rare Ava II allele was also associated significantly with an increased pressure–strain elastic modulus (stiffness) of the aneurysmal wall. In 14 patients of 1–1 genotype the median pressure–strain elastic modulus was 23·9 N/cm^2 compared with 42·0 N/cm^2 in 11 of 1–2 genotype (P = 0·008, Mann–Whitney U test) (*Figure 2*). Pressure–strain elastic modulus was not determined in any patient of 2–2 Ava II genotype.

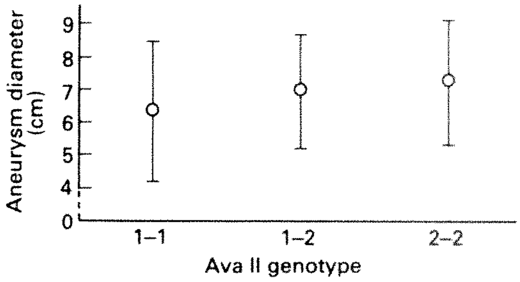

Figure 1 *Variation of aneurysm diameter with collagen III genotype. The mean(s.d.) diameter is given for each genotype determined by Ava II digestion. 1–1 Genotype,* n = *64; 1–2,* n = *50; 2–2,* n = *11. Presence of the rare (2) allele was associated with an increased aneurysm diameter* (P = *0·044, analysis of variance*)

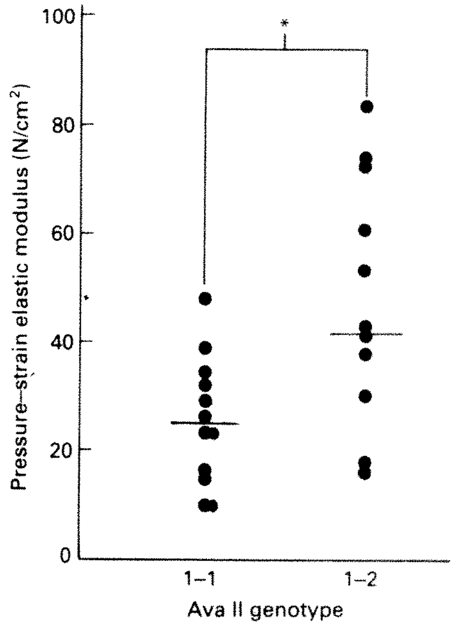

Figure 2 *Variation of pressure–strain elastic modulus with collagen III genotype. The median (interquartile range) value in patients of 1–1 Ava II genotype was 23·9 (16·5–32·6) N/cm^2 compared with 42·0 (30·5–73·0) N/cm^2 in those of 1–2 genotype.* *P = *0·008 (Mann–Whitney* U *test*)

Discussion

Patients with AAA are more likely to have an aneurysm elsewhere, for example in the femoral, popliteal or carotid arteries, indicating a general tendency for dilating aneurysmal disease. Other patients have stenosing lesions in the aorta, iliac and other distal arteries. Atherosclerosis is certainly the cause of these stenosing lesions but commonly is also present in aneurysmal disease. The elastic and other mechanical properties of the aorta and other arteries could influence whether, in the presence of ageing and atherosclerosis, an artery dilates or stenoses. Such mechanical properties may be under genetic control, since mutational change in components of arterial connective tissue is the cause of both arterial dilatation in Marfan's syndrome and the arterial fragility of Ehlers–Danlos type IV disease.

With ageing and disease, the elastin content of the aortic media decreases, thereby shifting the mechanical load of the pulse pressure from elastin on to collagen[9,12]. In this situation subtle variations in the structure or content of type III collagen could influence the mechanical properties of the aorta and hence its susceptibility to disease. The present results add weight to this hypothesis. For patients with AAA, polymorphic variation in the region 3′ to the type III collagen gene detected with the restriction enzyme Ava II was associated with both aneurysm diameter and pressure–strain elastic modulus. Although this polymorphism lies outside the type III collagen gene, it is detected using a collagen gene probe and so lies sufficiently close to the 3′ region of the gene to act as a marker for variation in this region. The presence of the rare Ava II allele was significantly less common in patients with aortoiliac stenosis than in those with AAA. These results are a clear indication of a genetic influence on disease in the ageing aorta. Such genetic influence may determine whether, in the presence of atherosclerotic risk factors, the aorta stenoses or dilates; it might also determine how rapidly an aneurysm grows.

In contrast, the results for the 531 Ala → Thr polymorphism and the 619 Gly → Arg mutation within type III collagen provide no support for the presence of a single common founder mutation in type III collagen predisposing to AAA. It is interesting that patients with distal arterial disease without a significant aortoiliac component have an increased frequency of Thr-531 in type III collagen. Again, this could indicate that subtle variation in collagen influences the mechanical properties of the ageing aorta and hence its susceptibility to disease.

In summary, an important contribution to the development of AAA may result from the influence of variation in the type III collagen gene on the mechanical stability of the ageing aorta. Whether possession of the rare Ava II allele of the type III collagen gene is associated with more rapid aneurysmal dilatation or rupture is being studied prospectively.

Previous studies have shown that overt intrahepatic tumours are associated with subtle changes in liver perfusion that can be measured directly using duplex colour Doppler sonography (DCDS). This study assessed the predictive value of DCDS in the early detection of occult colorectal hepatic metastases. Hepatic arterial and portal venous blood flow was measured in 50 control subjects and 135 patients with colorectal cancer, 67 with overt liver metastases and 68 with an apparently disease-free liver on the basis of computed tomography and laparotomy findings. The Doppler perfusion index (DPI), defined as the ratio of hepatic arterial to total liver bloodflow, was calculated. Clear separation of the DPI values of controls and those of patients with overt metastases was observed ($P < 0.0001$). Thirty-eight of the 68 patients with a disease-free liver also had an abnormally high DPI value. After 1 year of follow-up, 21 patients with an abnormally high DPI at the time of apparently curative primary resection had developed liver metastases and a further four had died without post-mortem examination. The 30 patients with normal DPI remain disease-free. The data suggest that DPI is of value in the early detection of occult liver metastases.

Colorectal cancer is the second most common malignancy in the UK, with 27000 new cases each year. About 25 per cent of patients have evidence of hepatic metastases at the time of presentation[1] and their prognosis is poor. Furthermore, for patients who have had an apparently curative resection of the primary tumour, the 5-year survival rate is only 50 per cent, with the majority dying from disseminated disease within the first 3 years. Finlay and McArdle[2] have shown that occult liver metastases are present in about 25 per cent of those who have undergone apparently curative resection. This finding has been supported by other workers[3] using intraoperative ultrasonography. The presence or absence of these liver metastases determines the likelihood of dying from disseminated disease.

The early detection of occult liver metastases is therefore important but appears to be beyond the resolution of current imaging techniques such as conventional ultrasonography, computed tomography (CT) and magnetic resonance imaging. There is a threshold size and contrast below which the differentiation between normal and abnormal tissue is impossible. Although recent advances in these cross-sectional imaging techniques have led to the detection of subcentimetre lesions, these are too small to have any characteristic morphological feature of diagnostic value and further follow-up with repeated radiological scanning is required.

There has been much interest in measurement of the subtle changes in hepatic perfusion associated with the presence of liver tumours. Previous studies using dynamic scintigraphy have shown that the presence of liver metastases can be diagnosed by measuring the ratio of hepatic arterial to total liver blood flow (the hepatic perfusion index) as described by Leveson and colleagues[4]. However, this technique has not gained support in clinical practice because of difficulties in the interpretation of data and lack of reproducibility[5]. Over the past 18 months a novel method has been developed to measure changes in liver perfusion using duplex colour Doppler sonography (DCDS). This is a more direct technique of non-invasive blood flow measurement, which should be more accurate. This study assessed the predictive value of DCDS in the early detection of occult colorectal hepatic metastases.

Patients and methods

Fifty healthy volunteers (age 23–75 years) and 135 patients with colorectal cancer (age 32–75 years) were studied. The technique for measuring hepatic arterial and portal venous blood flows has previously been described[6]. All subjects were examined in the supine position after 12 h of fasting. Using DCDS, the hepatic arterial and portal venous blood flows were calculated from the product of the measured time-average velocity of blood in the vessel and the time-average cross-sectional area of the lumen of the vessel. The total liver blood flow was taken as the sum of the hepatic arterial and portal venous blood flows. The Doppler perfusion index (DPI), defined as the ratio of the hepatic arterial to total liver blood flow, was calculated.

Anatomical variations were present in 20 of 67 patients (30 per cent) with liver metastases as confirmed by hepatic arteriography and in 16 of 68 (24 per cent) with an apparently 'clear' liver on the basis of DCDS only. Control subjects with anatomical variations were excluded from the study. The two main variations easily identified by DCDS in this study were: (1) both right and left hepatic arteries arising from the superior mesenteric artery; and (2) left hepatic artery arising from the coeliac axis and the right hepatic artery from the superior mesenteric artery. Sometimes an accessory right hepatic artery with its origin in the superior mesenteric artery could also be identified by the smaller calibre of the vessel. When hepatic arterial anatomical variation occurred, the total hepatic arterial blood flow was taken as the sum of the blood flows from the aberrant hepatic arteries.

Technique of Doppler flow measurement

A Diasonics Spectra scanner (Diasonics Sonotron, Bedford, UK), which contains duplex and colour Doppler facilities, was used with a 3·5-MHz convex phased linear-array probe. In the Doppler mode, ultrasound waves were emitted and received by a single 3·5-MHz probe at a frequency of 3 MHz with a repetition frequency of 3·7 kHz. It was possible to steer the Doppler beam to any location, and the angle between the beam and the vessel examined could be measured from the monitor. An angle range of 50–68° was used for velocity measurement. Spectral analysis was performed using fast Fourier

0007-1323/93/101249-03 © 1993 Butterworth-Heinemann Ltd

transformation and the Doppler shift signal was displayed on the monitor. The system was equipped with software to compute the time-average velocity from the velocity spectral display automatically, following placement of the calipers at the start and end of one or more cardiac cycles. The cross-sectional area of the vessel was measured by mapping the perimeter of the vessel lumen with a 'tracker ball'.

A transverse scan was made at the epigastrium to locate the common hepatic artery in its longitudinal axis. The Doppler cursor was placed over the lumen of the artery segment as near to the origin as possible, at the point where it first became horizontally straight. The Doppler sample volume and beam angle were adjusted and the time-average velocity calculated over four cardiac cycles. The cross-sectional area of the artery was measured at the same point at right angles to the vessel. Time-average cross-sectional area was calculated by taking the mean of the areas measured separately over four different cardiac cycles. The same parameters were obtained for the portal vein in a similar manner at the mid-level of the vein. All measurements were performed under respiratory suspension in expiration to allow optimal visualization of the portal vein and enable a more acute angle to be achieved for Doppler purposes. Each measurement was performed repeatedly until satisfactory spectral patterns were obtained. These measurements were carried out by an independent ultrasonographer with no knowledge of the preoperative CT and ultrasonography findings. No sonographic assessment of the liver parenchyma was made while performing the DPI measurement.

Conventional non-enhanced and enhanced dynamic CT was performed in all patients with colorectal cancer before operation using a GE 9800 CT scanner (Milwaukee, Wisconsin, USA). Enhanced scans were performed using a peripheral intravenous bolus injection (150 ml) of Ultravist 370 (iopromide; Schering Health Care, Burgess Hill, UK) administered by an Angiomat CT injector (Liebel-Flarsheim, Cincinnati, Ohio, USA).

Patients with an apparently disease-free liver on the basis of laparotomy and CT findings were subsequently followed by routine outpatient clinical examination, ultrasonography at intervals of 3 months, and annual CT (earlier if clinically indicated).

Informed consent was obtained from all subjects. Data were analysed using the Mann–Whitney *U* test.

Results

On the basis of CT and laparotomy findings, 67 patients had liver metastases and 68 an apparently curative resection. There was a significant increase ($P < 0{\cdot}0001$) in the time-average velocity and cross-sectional area of the hepatic artery in patients with liver metastases compared with controls. Hepatic arterial blood flow was therefore significantly higher ($P < 0{\cdot}0001$) in the group with metastases (*Table 1*). However, there was a significant reduction in the time-average velocity ($P < 0{\cdot}001$) and cross-sectional area ($P < 0{\cdot}0001$) of the portal vein in patients with hepatic metastases compared with the control group. The portal venous blood flow was significantly lower ($P < 0{\cdot}0001$) in patients with liver metastases than in controls (*Table 1*). No significant difference was demonstrated between these two groups in the total liver blood flow.

The upper limit of the normal range of DPI values was 0·25; the range for patients with hepatic metastases was 0·30–0·77. Clear separation of the DPI values was observed between controls and patients with overt liver metastases ($P < 0{\cdot}0001$) (*Figure 1*). The results for the 68 patients in the third group (those with an apparently disease-free liver) overlapped those of controls and patients with overt liver metastases. Thirty-eight of the 68 patients had an abnormally raised DPI. At the 1-year follow-up, 21 of these 38 patients had developed liver metastases, of whom nine had died. Two further patients had died with local recurrence of the primary tumour but hepatic metastases could not be excluded at the time of death. Another two patients died at home and no autopsy was carried out. Thirteen patients with an abnormal DPI have not yet shown evidence of dissemination and require further follow-up. The remaining 30 patients with a normal DPI are still alive and remain disease-free on the basis of clinical evidence, ultrasonography and CT. At 1 year of follow-up, excluding the four patients whose liver status was unknown, the sensitivity, specificity, and positive and negative predictive values of the test in the third group were 100, 70, 62 and 100 per cent respectively.

Of the 30 patients who had an apparently curative resection of the primary tumour with a normal DPI value, ten had Dukes' C, 19 Dukes' B and one Dukes' A disease. Of the 38 patients with an abnormal DPI value, 22 had Dukes' C and 16 Dukes' B tumours. Of the 21 patients who subsequently developed overt liver metastases within 1 year of follow-up, 18 had Dukes' C and three Dukes' B disease; vascular invasion by the primary tumour was present in six patients.

Discussion

The clinical value of qualitative data provided by duplex ultrasonography is widely recognized but there is still some discussion about the value of quantitative measurements. While the accuracy and reproducibility of flow measurements have been well documented *in vitro* and *in vivo* at research level, there is still some scepticism regarding its application in clinical practice. The wide variety of commercially available duplex scanners that have not been properly calibrated has led to inconsistency of quantitative data. Kimme-Smith and colleagues[7] have compared measurements of peak velocities obtained using 17 different scanners with values obtained from calibrated phantoms. The mean variation among the various systems was 23 per cent under identical conditions. Some units gave peak velocities that were > 100 per cent too high compared with calibrated peak velocities. The authors advised that quantitative measurements obtained using Doppler ultrasonography should be reported, with information on the calibration of the equipment.

The authors have previously demonstrated[8,9] the accuracy of duplex colour Doppler flowmetry *in vitro* and the reproducibility of the hepatic arterial and portal venous blood flow measurements *in vivo*. Following repeated measurements of the flow parameters in each vessel for five healthy volunteers, the mean coefficients of variation for time-average velocity, cross-sectional area and blood flow were 4·5, 6·1 and 7·6 per cent respectively. The potential sources of error involved are: (1) non-uniform insonation of the vessel; (2) spectral broadening; (3) angle correction; (4) area estimation; and (5) errors in the processing facilities of the system. However, some of these can be minimized by standardizing the technique used to make each measurement. Addition of a colour Doppler facility to the conventional duplex scanner is of great advantage in the precise assessment of vessel geometry and accurate identification of vessels of interest; it shows anatomical variations and allows a significant reduction in the duration of scanning. The technique is, however, operator dependent and a dedicated ultrasonographer is essential.

The arterial blood supply to the liver is quite variable. Although account was taken in the present study of anatomical variations when detected, underestimation of hepatic arterial blood flow would have occurred when the left hepatic artery and/or an accessory left hepatic artery arose from the left gastric artery, as they would not have been identified by DCDS. If that were the case in patients with an abnormal DPI, the true DPI value would be even higher and would, therefore, have remained abnormal. Underestimation of hepatic arterial flow could in theory lead to false-negative results, but no patient with a normal DPI has yet developed liver metastases.

Despite the potential sources of error involved in the technique, clear separation of the DPI values of all patients with overt liver metastases was observed compared with controls. This suggests that DCDS measurement of DPI can reliably detect patients with colorectal cancer and overt hepatic metastases. The upper limit of the normal range for the DPI is lower than the corresponding value for the hepatic perfusion index[4], which in theory measures the same blood flow ratio by dynamic scintigraphy. This presumably reflects the difference in technique; both may be subject to different types of systematic error. For example, the hepatic perfusion index may overestimate the true blood flow ratio because of dispersion of the tracer bolus in the splanchnic vascular bed.

The results of the third group of 68 patients who underwent apparently curative resection of the primary tumour are particularly interesting. Thirty-eight of these patients had abnormally high DPI values before laparotomy, and after 1 year of follow-up 21 had developed liver metastases, of whom nine had died. Furthermore, liver metastases may have been present in the other four patients who died. These initial data confirm the ability of DCDS measurement of DPI to detect occult liver metastases at the time when the patient first presents with colorectal cancer. Furthermore, the 30 patients who had normal DPI values showed no evidence of liver metastases after 1 year of follow-up, resulting in a negative predictive value of 100 per cent. Further follow-up to assess the long-term predictive value of the DPI is required. However, the implication is potentially far-reaching, especially at a time when the role of adjuvant therapy is still uncertain in the UK. About 50 per cent of patients undergoing curative resection do not require adjuvant therapy. Therefore, if patients at high or low risk could be identified reliably, adjuvant therapy could be administered on a selective basis. It has been suggested that adjuvant therapy should be regarded as standard practice in patients with Dukes' C carcinoma. If so, about 75 000 patients in Western Europe (including 8100 in the UK) and 45 000 in the USA could be expected to receive adjuvant therapy each year. Most regimens of systemic adjuvant chemotherapy are associated with varying degrees of toxicity and about 30 per cent of these patients would be expected to discontinue treatment prematurely because of toxicity[10]. The identification of the patients at low risk would prevent inappropriate treatment and avoid unnecessary morbidity.

In conclusion, the data suggest that measurement of the DPI by DCDS can reliably detect overt liver metastases and identify patients with occult liver metastases that will become clinically or radiologically apparent in the first year after operation.

Correspondence to:
Mr A. J. McMahon, University Department of Surgery, Western Infirmary, Glasgow G11 6NT, UK

As part of a randomized trial, ventilatory and arterial blood gas changes were assessed during open (n = *30*) *and laparoscopic* (n = *30*) *cholecystectomy. Measurements were made during anaesthesia before the start of surgery and at the time of removal of the gallbladder. Despite an increase in minute ventilation from a mean(s.d.) of 5·7(1·4) to 6·1(1·2) litres, mean(s.d.) arterial carbon dioxide tension* (P_{aCO_2}) *rose from 5·3(0·9) to 6·0(0·9) kPa during laparoscopic cholecystectomy. End-tidal carbon dioxide tension* ($P_{E'CO_2}$) *had poor precision in predicting* P_{aCO_2} *(95 per cent interval of agreement −0·61 to 1·93 kPa). Mean(s.d.) peak airway pressure increased from 17(4) to 23(4) cmH*$_2$*O. The mean* $P_{aCO_2} - P_{E'CO_2}$ *value did not change significantly, although there was significant within-patient variation. Arterial oxygen levels did not change significantly. By comparison, no clinically significant changes in ventilation or blood gas values occurred during open cholecystectomy. In conclusion, laparoscopic cholecystectomy requires a substantial but variable increase in minute ventilation to compensate for carbon dioxide absorption from the peritoneum.*

Until the advent of extended therapeutic procedures such as laparoscopic cholecystectomy, most laparoscopies were brief and were performed in young, fit patients. Ventilatory changes in these patients have been extensively studied and found to be clinically unimportant[1–4]. With the increasing popularity of minimally invasive general surgery, many laparoscopic procedures now require long periods of peritoneal insufflation and are often performed on patients who are older and have respiratory disease. Two recent studies[5,6] have suggested that in these circumstances greater ventilatory changes occur.

End-tidal carbon dioxide partial pressure ($P_{E'CO_2}$) monitoring is increasingly used during anaesthesia as an indirect measure of arterial carbon dioxide tension (P_{aCO_2}); the relationship between these two variables is therefore of considerable interest. The arterial–end-tidal P_{CO_2} difference, $P_{aCO_2} - P_{E'CO_2}$, depends on many factors including the relative distribution of ventilation and perfusion within the lung, and the functional residual capacity[7]. During laparoscopic procedures, changes in ventilation and perfusion distribution caused by basal lung compression might be expected to occur because of the pneumoperitoneum. Thus, $P_{aCO_2} - P_{E'CO_2}$ might be expected to change.

The present study assessed ventilatory and arterial blood gas changes during laparoscopic cholecystectomy (using open cholecystectomy as a control group), and assessed the accuracy of capnography in monitoring arterial carbon dioxide tension changes.

Patients and methods

This study was approved by the local hospital ethics committees. Informed consent was obtained from all patients, who were participating in a randomized trial comparing laparoscopic cholecystectomy and open cholecystectomy through a small subcostal incision. All patients undergoing elective cholecystectomy were considered for entry to the trial. Patients requiring emergency surgery, those with suspected bile duct stones and those with extensive previous upper abdominal surgery were excluded. Patients were randomized using numbered sealed envelopes. Thirty consecutive patients in each arm of the randomized trial were studied. Three patients in the laparoscopic group who required early conversion to open cholecystectomy were excluded.

Patients underwent general anaesthesia and were paralysed and ventilated. Anaesthetic techniques were similar in both groups; agents used were thiopentone or propofol for induction, suxamethonium for initial muscle relaxation, morphine and enflurane for maintenance, and atracurium besylate or vecuronium for muscle relaxation. An Ohmeda OAV 7750 ventilator (Ohmeda, Hatfield, UK) with a non-rebreathing circuit was used. Minute ventilation was recorded by a flow transducer on the expiratory side of the circuit. Peak airway pressure was recorded by an anaeroid pressure gauge in the ventilator. End-tidal carbon dioxide tension was measured throughout the operation using an infra-red analyser (Datex Capnomac Ultima; Instrumentation Corporation, Helsinki, Finland). The coefficient of variation for $P_{E'CO_2}$ measurement of values within the normal range is 0·2 per cent. Minute ventilation was adjusted to obtain $P_{E'CO_2}$ within the range 4·0–6·0 kPa. When $P_{E'CO_2}$ was stable, and just before the start of surgery, baseline recordings were made of minute ventilation, peak airway pressure, $P_{E'CO_2}$ and inspired oxygen fraction (F_{IO_2}). At the same time, an arterial blood sample was taken and analysed for oxygen tension (P_{aO_2}), carbon dioxide tension (P_{aCO_2}), and concentrations of hydrogen ion ([H$^+$]) and bicarbonate ([HCO$_3^-$]). The coefficient of variation for P_{aCO_2} measurements of values within the normal range is 1·4 per cent.

In patients undergoing laparoscopic cholecystectomy, pneumoperitoneum was achieved with carbon dioxide insufflation through a Veress needle to a maximum pressure of 15 mmHg. No patient developed surgical emphysema caused by a misplaced Veress needle. The operation was performed with the patient either horizontal or with a slight head-up tilt. During surgery, ventilation settings in both groups were adjusted according to changes in $P_{E'CO_2}$ (arterial blood gas results were not available to the anaesthetist). At the time of removal of the gallbladder, all measurements including arterial blood gas sampling were repeated.

Statistical analysis

Comparison between groups was made using Student's unpaired *t* test and within groups using the paired *t* test. The 95 per cent confidence intervals (c.i.) of the range of $P_{aCO_2} - P_{E'CO_2}$ values were calculated to assess the accuracy of capnography in monitoring P_{aCO_2} changes[8]. Correlations were tested with Pearson linear regression analysis.

Results

The groups were well matched for preoperative patient characteristics (*Table 1*). Results are summarized in *Tables 2* and *3*.

Baseline results

On baseline measurements, the two groups were well matched for ventilatory and blood gas values. $P_{E'CO_2}$ was of low accuracy in predicting P_{aCO_2}: the 95 per cent interval of agreement was −0·61 to 1·93 kPa.

Measurements at time of gallbladder removal

The mean (range) time between beginning surgery and the second set of measurements was 40 (20–95) min in patients undergoing open cholecystectomy, compared with 61 (30–115) min in those having the laparoscopic procedure ($t = 4·1$, $P < 0·001$). All patients remained haemodynamically stable throughout surgery.

In the open cholecystectomy group, no clinically significant changes occurred in ventilatory or arterial blood gas values (*Table 2*).

For laparoscopic cholecystectomy, induction of a carbon dioxide pneumoperitoneum resulted in a progressive rise in $P_{E'CO_2}$ in the majority of patients. Despite a significant increase in minute ventilation, P_{aCO_2} and arterial $[H^+]$ both increased significantly. There was no correlation between the duration of pneumoperitoneum and the rise in either minute ventilation ($r = 0·27$, $P = 0·15$) or P_{aCO_2} ($r = 0·25$, $P = 0·18$). Pneumoperitoneum was also associated with a mean rise of 6 cmH_2O in peak airway pressure. There were no significant changes in $P_{aCO_2} - P_{E'CO_2}$, P_{aO_2} or F_{iO_2}.

As in baseline measurements, at the time of gallbladder removal $P_{E'CO_2}$ was of low accuracy in predicting P_{aCO_2} (95 per cent interval of agreement −0·4 to 1·6 kPa in both groups). Furthermore, there was poor concordance between $P_{aCO_2} - P_{E'CO_2}$ at the two time points (95 per cent interval of agreement between the baseline and second measurement for open cholecystectomy was −0·8 to 1·21 kPa and for the laparoscopic procedure −1·5 to 1·3 kPa).

Discussion

There have been numerous studies of ventilatory changes during laparoscopic gynaecological procedures with carbon dioxide pneumoperitoneum. Carbon dioxide absorption during laparoscopy performed under local anaesthesia results in an increased respiratory drive, with minute ventilation increasing by a mean of 1 l/min to maintain P_{aCO_2} within the normal range[9]. On the other hand, during laparoscopy under relaxant general anaesthesia with fixed minute ventilation volume, mean P_{aCO_2} is reported[1,4,10–12] to rise by 0·6–1·4 kPa.

There are only two published studies of blood gas changes during laparoscopic cholecystectomy[5,6]. Wittgen *et al.*[5] compared changes in 20 normal patients with those in ten with cardiorespiratory disease. During laparoscopic cholecystectomy, P_{aCO_2} rose by 0·8 kPa in the normal patients (without increasing ventilation), whereas in those with cardiopulmonary disease P_{aCO_2} rose by 2·0 kPa despite an increase in minute ventilation of 1·2 litres. The corresponding alterations in $P_{E'CO_2}$ were much lower and did not fully reflect the changes in P_{aCO_2}: in normal patients $P_{E'CO_2}$ increased by only 0·3 kPa, while in those with cardiorespiratory disease it rose by only 0·6 kPa. In contrast, in the present study and in an analysis of gynaecological laparoscopy[10], mean $P_{aCO_2} - P_{E'CO_2}$ did not change significantly with carbon dioxide pneumoperitoneum. Nevertheless, the present finding of poor concordance between the baseline value of $P_{aCO_2} - P_{E'CO_2}$ and the value at the end of the procedure supports the conclusion of Wittgen *et al.*[5] that end-tidal measurement of P_{CO_2} is a poor indicator of changes in P_{aCO_2}. Marked within-patient variability in $P_{aCO_2} - P_{E'CO_2}$ during anaesthesia has also been shown in a study of patients undergoing major surgery[13]. Indeed, within-patient variations in $P_{aCO_2} - P_{E'CO_2}$ were similar to or greater than inter-patient differences.

In the only other study of blood gas and ventilatory changes during laparoscopic cholecystectomy, Liu *et al.*[6] found that $P_{E'CO_2}$ and P_{aCO_2} both increased by a mean of 1·4 kPa during laparoscopic cholecystectomy, with 13 of 16 patients requiring an increase in minute ventilation to maintain $P_{E'CO_2}$ below 6 kPa. They claimed that there was good agreement between paired $P_{E'CO_2}$ and P_{aCO_2} measurements, but their data do not support this statement. On analysing their results, we calculate that the 95 per cent interval of agreement between P_{aCO_2} and $P_{E'CO_2}$ was $-0{\cdot}42$ to 1·08 kPa.

In a pig model of laparoscopic cholecystectomy, P_{aCO_2} increased by 1·9 kPa and carbon dioxide output by 30 per cent of baseline values[14]. In a canine model of prolonged laparoscopy (2 h), the effects of carbon dioxide and helium pneumoperitoneum were compared[15]. Even with a 57 per cent increase in minute ventilation to maintain constant $P_{E'CO_2}$, carbon dioxide pneumoperitoneum was associated with a significant rise in P_{aCO_2} and $P_{aCO_2} - P_{E'CO_2}$. The rise in minute ventilation requirement, P_{aCO_2} and $P_{aCO_2} - P_{E'CO_2}$ was greater in dogs with papain-induced pulmonary emphysema, supporting the findings of Wittgen *et al.*[5] in patients with pulmonary disease undergoing laparoscopic cholecystectomy. Intraoperative blood gas monitoring may be advisable in patients with severe respiratory disease[5], as they may have larger differences between P_{aCO_2} and $P_{E'CO_2}$ and a greater tendency to retain carbon dioxide.

Helium has recently been suggested as an alternative insufflation gas to carbon dioxide in patients with severe respiratory disease[15,16]. It is inert, non-combustible and cheap; its only drawback is that it is relatively insoluble. To reduce the risk of insoluble gas vascular embolism with helium pneumoperitoneum, the open technique of laparoscopy might be used[17], which avoids the risk of insufflation through a misplaced Veress needle. Alternatively, the initial pneumoperitoneum could be created using carbon dioxide and, once pneumoperitoneum is safely established, carbon dioxide could be replaced by helium as the maintenance gas.

During laparoscopic procedures, changes in ventilation and perfusion distribution might be expected to occur because of the raised intra-abdominal pressure. However, in this study $P_{aCO_2} - P_{E'CO_2}$ and P_{aO_2} during pneumoperitoneum were not significantly different from values observed before insufflation or those in patients undergoing open surgery.

In conclusion, laparoscopic cholecystectomy with carbon dioxide pneumoperitoneum is associated with a significant increase in carbon dioxide output, requiring a significant but variable increase in minute ventilation to prevent hypercarbia. $P_{E'CO_2}$ is of low accuracy in predicting P_{aCO_2}. We therefore suggest that ventilation be increased to maintain $P_{E'CO_2}$ towards the lower end of the normal range (4–5 kPa).

This randomized study compared the metabolic responses to laparoscopic cholecystectomy ($n = 10$) *and minilaparotomy cholecystectomy with a 5–7-cm incision* ($n = 10$)*. Venous blood samples were taken before operation and at 3, 6, 9, 12, 18, 24, 48, 72 and 168 h after incision and analysed for levels of C-reactive protein, interleukin 6, cortisol, albumin, transferrin, iron, fibrinogen, fibrin degradation products and polymorphonuclear elastase, and for neutrophil and lymphocyte counts. Urine samples (24 h) were analysed for urea, creatinine, 3-methylhistidine and catecholamines. The magnitude of the metabolic changes from baseline levels was quantified by calculating areas under each individual curve. A significant metabolic response with a similar time course and magnitude of changes occurred after laparoscopic and minilaparotomy cholecystectomy but with wide variation in magnitude between individuals.*

The stress of surgery leads to production of cytokines and acute-phase proteins, increases in the levels of 'stress' hormones, loss of muscle protein, greater vascular permeability and changes in white cell count subsets. Some of these responses are a homoeostatic defence mechanism, but others such as the catabolic state are thought to be deleterious[1]. Many investigators[2–6] have therefore tried to find ways of reducing the metabolic response to surgery.

The use of a small transverse incision for open cholecystectomy (minilaparotomy) has been shown to result in a more rapid postoperative recovery than a standard laparotomy[7–13]. Laparoscopic cholecystectomy is replacing the open operation as the procedure of choice for symptomatic cholelithiasis[14]. The advantages claimed are less postoperative pain[15] and a more rapid return to normal activity[14].

The magnitude of the metabolic response to surgical trauma is proportional to the degree of injury[16–19], and the reduction of 'access trauma' by laparoscopic techniques might therefore diminish the response[20]. Diagnostic laparoscopy alone is associated with a substantial hormonal and glycaemic response, which may be evoked by the stimulus of peritoneal distension[21]. The magnitude of the metabolic response correlates with the duration of surgery[17,22], which is longer for laparoscopic than open cholecystectomy[23].

This study compared the pattern and magnitude of the metabolic response to injury after laparoscopic and minilaparotomy cholecystectomy as part of a randomized trial evaluating the two procedures[24,25].

Patients and methods

The trial was approved by the local hospital ethical committees and informed consent obtained from all patients. Those with suspected common bile duct stones were excluded. Detailed metabolic studies were performed in ten consecutive patients in each arm of the trial. Patients requiring conversion to open cholecystectomy, those with medical conditions or receiving treatment that might result in an altered metabolic response to surgery and patients who developed complications were excluded. The median (range) age of patients undergoing laparoscopic cholecystectomy was 58 (30–71) years and in the minilaparotomy group 44 (25–70) years. There was one man in each group.

Anaesthetic techniques were similar in the two groups. Minilaparotomy cholecystectomy was performed through a 5–7-cm subcostal incision[11]. Laparoscopic cholecystectomy was performed by a four-cannula technique using electrocautery. Wounds in both groups were infiltrated with 20 ml 0·5 per cent bupivacaine at the end of the procedure. The median operating time was longer for laparoscopic cholecystectomy (65 *versus* 46 min, $P = 0{\cdot}01$). After operation, patients received morphine by a disposable patient-controlled analgesia device[26] (PCA infusor system; Baxter Healthcare, Thetford, UK). For the first 24 h after operation, patients were given intravenous fluids (1 litre normal saline, 2 litres 5 per cent dextrose), and thereafter allowed free fluids and a normal diet. All patients made an uneventful postoperative recovery.

Blood was collected from an indwelling venous cannula on the morning of surgery (before premedication), and at 3, 6, 9, 12, 18, 24, 48, 72 and 168 h after incision. Urine samples (24 h) were collected the day before surgery, and over the first, second, third and seventh days after operation.

The level of the cytokine interleukin (IL) 6, which is thought to play a central role in the development of the metabolic response[27], was measured by the hybridoma growth stimulation assay using the mouse B cell hybridoma 7TD1 line[17,22,28]. Cell numbers were evaluated colorimetrically using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (thiazolyl blue)[29]. Standardization[30] was performed using recombinant IL-6 (National Institute of Biomedical Standards and Controls, Potters Bar, UK). Serum samples were heat-treated to inactivate any inhibitors. The detection limit was 14 units/ml and the coefficient of variation 19 per cent.

Levels of the positive acute-phase proteins, C-reactive protein (CRP) and fibrinogen, and of the negative acute-phase proteins, albumin and transferrin (falls in which reflect increased vascular permeability and loss to the tissue spaces[31]), were measured by nephelometry. The detection limit for serum CRP was 5 mg/l. Serum iron, levels of which fall after surgery[32], was measured colorimetrically using a Hitachi 737 analyser (Boehringer Mannheim, Mannheim, Germany).

Neutrophil and lymphocyte counts were determined with a Coulter Blood Analyser (Coulter, Basingstoke, UK). Levels of plasma cross-linked fibrin degradation products (FDPs), a measure of fibrin turnover, were determined using an enzyme-linked immunosorbent assay (AGEN; Parsippany, New Jersey, USA). The cortisol concentration was measured by fluorescence polarization immunoassay. Levels of polymorphonuclear elastase, which is released by activated neutrophils[33], were measured using the polymorphonuclear elastase IMAC immunoactivation kit (Diagnostica Merk, Frankfurt, Germany).

Urinary 3-methylhistidine concentration, an indicator of muscle protein breakdown[34], was measured by ion-exchange chromatography with ninhydrin detection. Urinary creatinine levels were determined using the alkaline picrate reaction and urea measured electrochemically using a Beckman CX-3 instrument (Beckman, High Wycombe, UK). Urinary nitrogen was calculated on the basis that urea loss comprises 80 per cent of total nitrogen loss.

Because of different collection conditions, urine for catecholamine measurement had to be collected from a second group of 20 patients, ten in each arm of the study, with median (range) ages 56 (27–72)

years in the laparoscopic group and 45 (19–82) years in the minilaparotomy group. (There were no men undergoing laparoscopic cholecystectomy and two having the minilaparotomy operation.) Urinary catecholamine levels were measured using high-performance liquid chromatography with electrochemical detection[35].

Peak expiratory flow rate was measured the day before and 24 h after operation with a Respiradyne pulmonary function monitor (Sherwood Medical, Crawley, UK). Analgesia consumption over the first 24 h was evaluated using patient-controlled delivery of morphine and pain assessed by a linear analogue score at 24 h.

Statistical analysis

To produce summary measures[36], each parameter was plotted against time and the area under the curve calculated individually for each patient using a program on a personal computer. For the two negative acute-phase reactants, albumin and transferrin, falls from preoperative values were plotted. Areas under the curves in the two groups were compared using the Mann–Whitney *U* test. The magnitude of changes in each metabolic variable (areas under the curve) were compared by the Pearson correlation coefficient (r). Values of white cell counts, urinary nitrogen, 3-methylhistidine and catecholamines in the two groups were compared at each time point using the Mann–Whitney *U* test with the Bonferroni correction as appropriate. Comparison of postoperative and preoperative catecholamine and 3-methylhistidine levels was performed with the Wilcoxon matched pairs test with the Bonferroni correction.

Results

The time courses of some of the metabolic changes measured are shown in *Figure 1*. Similar time courses of metabolic changes occurred in the two groups.

The calculated areas under the curves for the various parameters measured are shown in *Table 1*. There were no significant differences in the magnitude of the changes between the two groups. Patients undergoing laparoscopy, however, had better postoperative pulmonary function, consumed less morphine and had lower pain scores than those receiving minilaparotomy (*Table 2*).

There were no significant differences in urinary nitrogen loss (data not given). Food intake was not measured, therefore nitrogen balance could not be calculated, but both groups started eating on the first day. After operation, urinary 3-methylhistidine levels did not differ significantly from preoperative values and were all within the normal range (data not given).

There were no significant intergroup differences in catecholamine levels at the three time points with or without the Bonferroni correction (data not given).

There were significant associations between the response areas of several metabolic variables, in particular IL-6, CRP and polymorphonuclear elastase levels ($r > 0·75$, $P < 0·001$). There was also a strong correlation between falls in albumin and transferrin concentrations ($r = 0·69$, $P < 0·001$). A weak correlation was found between duration of surgery and IL-6 response ($r = 0·50$, $P = 0·04$), but there were no correlations between pain scores and pulmonary function and the metabolic variables.

Table 1 *Metabolic changes expressed as area under the curve*

	Cholecystectomy		
	Minilaparotomy	Laparoscopic	P*
C-reactive protein (mg/l × h × 10^2)	84 (15–359)	48 (13–365)	0·13
Interleukin 6 (pg/ml × h × 10^2)	135 (66–212)	117 (54–336)	0·76

Discussion

This study demonstrated a significant metabolic response to laparoscopic and minilaparotomy cholecystectomy, with no significant differences between the two types of surgery. The laparoscopic operation, however, results in less postoperative pain than minilaparotomy cholecystectomy[24], a smaller reduction in pulmonary function after operation, better postoperative oxygen saturation[25] and a more rapid return to normal activity[37]. There were no correlations between postoperative pain and pulmonary function, and the magnitude of the metabolic response; this concords with the finding that elimination of postoperative pain by epidural infusion of bupivacaine does not significantly alter the metabolic response to cholecystectomy[2,4]. Therefore pain after surgery is only one of a number of factors affecting the magnitude of the metabolic response.

The metabolic effect of minilaparotomy cholecystectomy has not been described previously. The present peak CRP response to minilaparotomy was within the range reported after standard open cholecystectomy[17,22,38–42] and the IL-6 response to both operations was similar to that after standard cholecystectomy using the same bioassay[43]. The falls in albumin and transferrin levels and the iron:transferrin ratio were similar to those after standard cholecystectomy[32]. The peak cortisol response to both operations was lower than that reported after standard cholecystectomy in several studies[3,4,42,44]. Three recent papers compared selected aspects of the metabolic response to laparoscopic and standard open cholecystectomy, using historical[38] and non-randomized[39,44] controls. The CRP responses to laparoscopic cholecystectomy reported in two[38,39] were lower than those in the present study. Using an immunoradiometric assay, Joris *et al.*[38] found lower IL-6 levels after laparoscopic cholecystectomy, although measurements were made at only three time points and the control group was historical. Two of these three studies showed a similar cortisol response after open and laparoscopic cholecystectomy[38,44]. Catecholamine changes have not shown a consistent pattern[38,39].

The sequential time course of IL-6, which preceded the rise of CRP and fibrinogen levels, and the strong correlation between these three markers is consistent with this interleukin being the primary stimulus to the acute-phase response[27]. Polymorphonuclear elastase values were raised throughout the postoperative period compared with preoperative levels, but changes were modest compared with those seen in severe sepsis[45]. Although monocytes, endothelial cells and fibroblasts are thought to be the major *in vivo* source of IL-6, some recent evidence suggests that circulating neutrophils contribute significantly to IL-6 production[46]. The strong correlation between changes in IL-6 and polymorphonuclear elastase (which is released by activated neutrophils[33]) and the immediate rise in polymorphonuclear elastase found in the present study are consistent with this hypothesis.

Laparoscopic cholecystectomy does not reduce the metabolic response compared with open surgery, despite less postoperative pain and more rapid recovery. Factors other than metabolic response may be important in determining postoperative recovery.

Acknowledgements

This study was funded by the Chief Scientist Office of the Home and Health Department of the Scottish Office. The authors are also grateful to Glaxo Laboratories Limited for additional funding. Dawn Watson and Frazer Davidson (Department of Biochemistry, Crosshouse Hospital, Kilmarnock) performed the catecholamine assays. Dr Gordon Murray (then Reader in Medical Statistics, Glasgow University) provided statistical advice.

Multidrug-resistant (MDR^+) cancer cells have the ability to grow in the presence of cytotoxic concentrations of antineoplastic drugs as a result of possessing the transmembrane drug efflux pump p-glycoprotein. The MDR^+ colonic cancer cell line LoVoDx (derived from the drug-sensitive line LoVo) was tested for sensitivity to lymphokine-activated killer (LAK) cell-mediated toxicity. LAK cells were cultured from patients with colonic cancer and from matched controls with benign disorders. LAK cells from patients with cancer were as effective as those from controls in mediating cytotoxicity. The MDR^+ cell line was significantly more sensitive to LAK cell-mediated cell killing than its parental drug-sensitive line LoVo ($P < 0.05$)*. These results indicate a possible role for adoptive immunotherapy in MDR^+ tumours expressing p-glycoprotein.*

Multidrug resistance is the acquisition of resistance to a spectrum of antineoplastic agents by a cell[1] and is frequently associated with expression of p-glycoprotein[1,2]. This is a 170-kDa cell-surface glycoprotein that functions as an energy-dependent drug efflux pump[2,3]. Cells expressing p-glycoprotein have the ability to extrude certain anticancer drugs much more rapidly than those not possessing it, thus minimizing their exposure to the drugs' toxic effects. This phenomenon may limit the effectiveness of treatment in a significant number of tumour types with a drug-resistant clone[3,4]. Therapeutic strategies to circumvent this effect include the use of chemotherapeutic agents not affected by the multidrug resistance phenotype, such as cisplatin or methotrexate, or to utilize agents that reverse multidrug resistance, such as verapamil or cyclosporin analogues[5,6].

Adoptive immunotherapy does not depend on chemosensitivity for antitumour activity[7,8]. Treatment of tumours with a subpopulation of multidrug-resistant (MDR^+) cells with combined chemotherapy and immunotherapy might be more successful if the cells unaffected by chemotherapy were sensitive to cell-mediated cytotoxicity. Although several studies have examined the sensitivity of MDR^+ tumour cell lines to lysis by lymphokine-activated killer (LAK) cells from healthy volunteers[9,10], none has so far addressed the issue of whether these findings apply to patients with tumours. This study examines the ability of LAK cells obtained from patients with colorectal cancer to lyse the human colorectal cancer cell line LoVo and its MDR^+ derivative LoVoDx. The cytotoxicity of effector cells derived from tumour-bearing patients with those from healthy controls is also compared.

Materials and methods

Cell lines

LoVoDx is derived from LoVo that has been subjected to gradually increasing doses of doxorubicin and has developed the MDR^+ phenotype, expressing p-glycoprotein at high levels. LoVoDx was maintained in logarithmic growth in Ham's F12 culture medium plus 100 ng/ml doxorubicin. LoVo and LoVoDx were gifts from Dr M. Grandi (Farmitalia Carlo Erba, Milan, Italy).

CEM is a human T cell leukaemia cell line. CEMV1b is a vinblastine-resistant subline that expresses p-glycoprotein at high levels. CEMV1b was grown in RPMI L654D medium plus vinblastine 100 ng/ml. (CEM and CEMV1b were gifts from Dr S. Brennan, Centocor, Malvern, Pennsylvania, USA.) CEMV1b and LoVoDx were grown in drug-free medium for 3 weeks before being used as targets in cytotoxicity assays to avoid the confounding influence of doxorubicin or vinblastine in the experiment. Using flow cytometry with the C219 monoclonal antibody (Centocor) directed against p-glycoprotein on MDR^+ cells, the cultured cells were found to express the glycoprotein at the same levels, indicating no significant loss of multidrug resistance over this interval.

Interleukin 2-activated killer cells

Peripheral blood lymphocytes were isolated by Ficoll–Hypaque (Pharmacia, Milton Keynes, UK) gradient from venous samples taken from controls and patients with colonic cancer. To generate LAK cells the lymphocytes were cultured in RPMI 1640 enriched with 10 per cent fetal calf serum, 2 mmol/l glutamine, 100 units/ml penicillin and 100 μg/ml streptomycin, at 2×10^6 cells/ml for 3–5 days in the presence of recombinant interleukin (IL) 2 (Eurocetus, Amsterdam, The Netherlands) at a concentration of 1000 units/ml.

Cytotoxicity assay

A standard 4-h ^{51}Cr release assay was used. Target cells were prepared from LoVo, LoVoDx, CEM and CEMV1b cell lines. Some 10^4 ^{51}Cr-labelled cells were placed in each well of a round-bottomed 96-well plate and effector:target ratios from 100:1 to 12·5:1 employed. When 4 h had elapsed, 100-μl aliquots of the supernatant were aspirated and counted in a γ counter. Experimental release was calculated for each sample. The spontaneous release was calculated for wells to which culture medium alone was added and the maximum release calculated for wells to which 5 per cent Lipsol (LIP, Shipley, West Yorkshire, UK) had been added. Percentage specific lysis was calculated according to the formula:

$$\text{Percentage specific lysis} = \frac{\text{experimental release} - \text{spontaneous release}}{\text{maximum release} - \text{spontaneous release}} \times 100$$

CEM and CEMV1b were used for comparison, as previous data showed them to be differentially sensitive to LAK-mediated cytotoxicity. The experiments were carried out in triplicate.

Study population

The patients were immediately preoperative inpatients with primary tumours ($n = 6$) or known postoperative recurrence ($n = 3$). The controls were matched inpatients ($n = 7$) undergoing minor elective surgery for benign disorders.

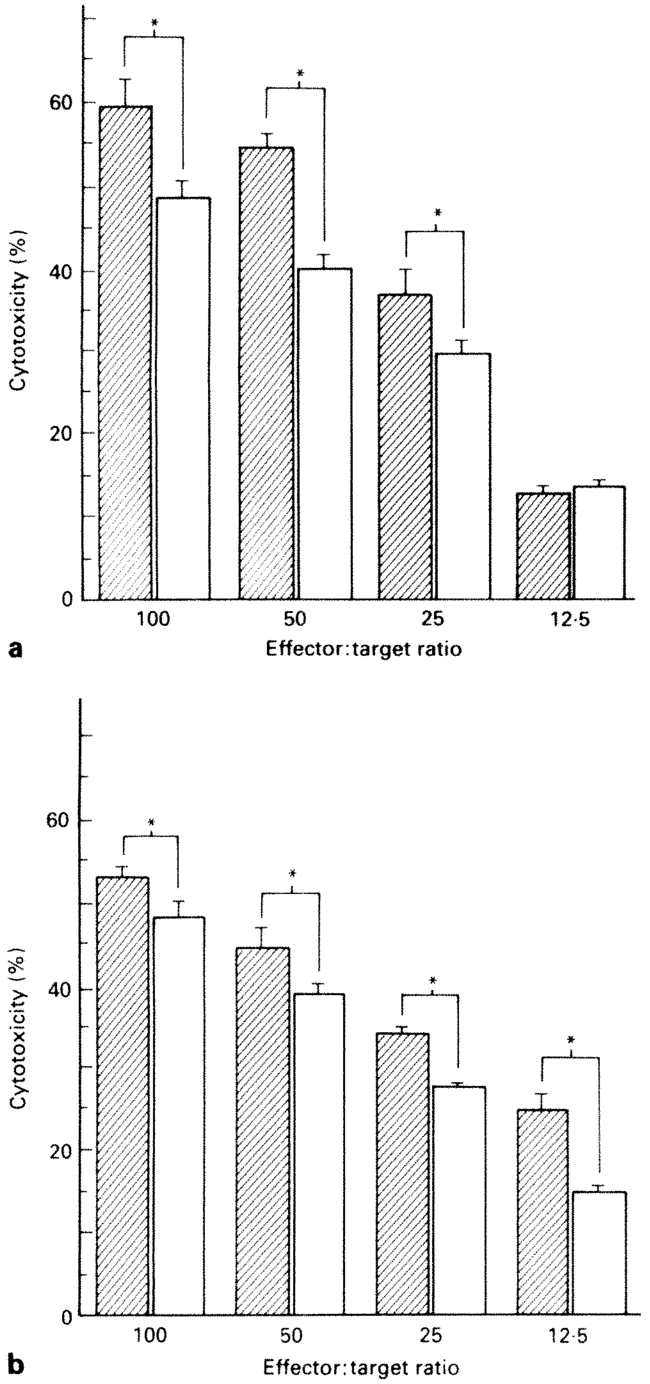

Figure 1 *Mean(s.e.m.) percentage specific lysis of colonic cell lines as assessed by ^{51}Cr-release cytotoxicity assay using lymphokine-activated killer cells from* **a** *patients with cancer and* **b** *controls.* ▨, *Multidrug-resistant LoVoDx;* □, *parental line LoVo.* *P < 0·05 *(two-way ANOVA)*

Statistical analysis

The differences between cell lines, and patients and controls were subjected to two-way analysis of variance and a Duncan's test of individual significance. Results are expressed as mean(s.e.m.).

Results

IL-2-stimulated effector cells mediated a high level of cell killing in both the colonic and leukaemic cell lines. There was a statistically significant higher sensitivity to LAK cell cytotoxicity in MDR$^+$ than MDR$^-$ cells ($P < 0.05$); this was seen in both the leukaemic and colonic cell lines. The LAK cells from patients with cancer were equally effective as those from normal controls. The results of the cytotoxicity assays on the colonic cell lines are shown in *Figure 1* and on the leukaemic lines in *Figure 2*.

Discussion

Multidrug resistance was first described by Juliano and Ling[1], who detected the p-glycoprotein in a Chinese hamster ovary cell line in 1976. The p-glycoprotein is an ATP-dependent active transport system that extrudes certain hydrophobic molecules from the cell[2,3]. In several studies with animal models a combination of chemotherapy with immunotherapy has been shown to produce more effective tumour regression than either alone. MDR$^+$cells may differ from their MDR$^-$ counterparts in their sensitivity to cell-mediated cytotoxic damage[11,12]. The present study assessed the sensitivity to cell-mediated cytotoxicity of a MDR$^-$ cell line and its parenteral MDR$^-$ line, and compared the effectiveness of LAK cells from patients with benign disorders with those from patients bearing a tumour of the same tissue of origin.

The results show that the presence of the multidrug resistance p-glycoprotein on the surface of the LoVoDx cancer cell was associated with an increase in sensitivity to LAK cell cytotoxicity. The mechanism by which this increase in sensitivity occurs is unclear. This study also shows that the phenomenon was present when the cytotoxic cells came from patients suffering the malignancy from which the cell line was derived. Further assessment of this form of therapy in animal experiments and clinical trials may therefore be possible.

Exposure to agents that reverse drug resistance has no effect on the sensitivity to cell-mediated killing[10]. Blocking the extracellular component of p-glycoprotein with a monoclonal antibody, making it less accessible to antigen-recognizing moieties on cytotoxic LAK cells, has no effect on the amount of cell killing achieved[10]. Down-regulating the expression of p-glycoprotein by use of antisense oligodeoxynucleotides to multidrug resistance gene 1 RNA, which causes marked reduction in surface p-glycoprotein levels, has failed to alter the sensitivity of cells to LAK-mediated cytotoxicity[10]. The use of agents that block the pump action of p-glycoprotein, such as verapamil, has failed to produce a change in sensitivity to cell-mediated killing, despite reversing the resistance to cytotoxic drugs[10]. These findings support the view that it is not as a direct result of the expression of p-glycoprotein on the cell surface that MDR^+ cells are more sensitive to cell-mediated cytotoxicity.

The physical properties of MDR^+ cell membranes are different[13] and this may cause increased susceptibility to cytotoxins released by activated killer cells. The level of expression of the surface glycoprotein and its messenger RNA are very high in resistant cell lines and tumours. This utilization of a large part of the cell's synthetic pathways with a superspecialized function might be associated with loss or diminution of other protective mechanisms.

Salmon *et al.*[3] have shown that MDR^+ leukaemia and myeloma cell lines demonstrating acquired multidrug resistance are more sensitive to the toxic effects of recombinant tumour necrosis factor (TNF) in clonogenic assays. The release of cytokines such as TNF by LAK cells may account partly for the increase in sensitivity to LAK-mediated cytotoxicity observed in this set of experiments. The present data show that treatment with immunochemotherapy of tumours containing clones with pleiotropic resistance to chemotherapeutic agents may be of therapeutic benefit.

Long-term results of a single protocol for thrombolysis in acute lower-limb ischaemia

A. E. B. Giddings, M. S. Quraishy and W. J. Walker*

*Departments of Surgery and *Radiology, Royal Surrey County Hospital, Egerton Road, Guildford GU2 5XX, UK*

Correspondence to:
Mr A. E. B. Giddings

In a prospective study, 78 of 157 patients with acute lower-limb ischaemia were considered suitable for thrombolysis. The immediate and 4-year results of 52 patients managed by a single protocol are reported. Of 34 patients alive at 4 years, 23 had limb salvage. Initial treatment produced effective lysis in 38 patients (73 per cent) with significant benefit in 35 (67 per cent); that benefit was sustained for a minimum of 4 years in 30 patients (58 per cent). Seven of the 18 deaths by 4 years occurred within 30 days. Amputation was carried out in six patients within 30 days and in five during the next 4 years. Delayed amputation followed persistent distal occlusion or progression of distal disease. No death or amputation was caused by complication of treatment. In selected patients the risks of thrombolysis can be reduced to an acceptable level by personal supervision and a strict protocol. In survivors, limb salvage is generally sustained for at least 4 years.

About 25 patients from this district of 200000 people present annually with acute limb ischaemia. The early mortality rate commonly exceeds 15 per cent and up to 30 per cent of patients require amputation[1]. Amputation for ischaemia involves high cost, a significant loss of independence, a poor quality of life and shortened survival after operation. Every effort must be made to save the limb in patients with no neurological damage who are likely to survive. Management options include anticoagulation with medical support, surgical intervention and thrombolysis, but the precise indications for each treatment have yet to be defined and outcome is not necessarily improved by increased intervention[2]. The causes of acute ischaemia are changing, with a decline in the incidence of systemic embolism and a rise in the incidence of arterial thrombosis.

This change in the cause of ischaemia, together with new developments in catheters and the advent of new thrombolytic agents, make the design of a controlled trial difficult. Several centres have published early results suggesting an improvement in the effectiveness and safety of thrombolysis as experience increases. These reports of initial success need now to be qualified by an assessment of long-term outcome.

Since 1982, all patients presenting to the Royal Surrey County Hospital with acute limb ischaemia have been assessed by a vascular surgeon (A.E.B.G.) and an interventional radiologist (W.J.W.) who have also carried out all procedures. In 1988, the present authors published a protocol for the safe treatment of acute lower-limb ischaemia with intra-arterial streptokinase and surgery, and described the initial results[3]. The present paper reports a long-term follow-up of that treatment.

Patients and methods

A total of 157 patients with acutely ischaemic limbs admitted between 1982 and the end of 1988 were studied prospectively to establish long-term outcome. Of these patients, 23 (15 per cent) were admitted with an acute white leg, suggesting systemic embolism, and were managed by immediate balloon-catheter embolectomy. Fifty-six patients (36 per cent) presented with subacute arterial thrombosis and were treated with heparin, medical support and elective investigation. The remaining 78 patients (50 per cent) were considered suitable for thrombolysis.

The first 26 patients so treated were the subject of an earlier report while the treatment protocol was being developed[4]. These and the next 44 patients were reported[3] in 1988. A further eight patients have now been added to the 44 previously reported. All 52 patients, who are the subject of the present report, have been treated with a single (Guildford) protocol and all survivors followed for a minimum of 4 years. Follow-up ranged from 0 to 89 months; the mean for all 52 patients was 45·1 months.

Data were obtained from clinical follow-up except for two patients. One of these was treated for peripheral arterial thrombosis after a myocardial infarction. The patient's limb was saved by thrombolysis and an irregular popliteal artery, thought to be the cause of the thrombosis, was noted. He was treated by anticoagulation and subsequently left hospital alive but cannot now be traced. The second patient lost to follow-up underwent satisfactory lysis for an arterial thrombosis. Lysis was followed by a successful femoropopliteal bypass, which is known to have remained patent for at least 2 years until contact was lost.

Results

Lysis was considered effective, removing between 70 and 100 per cent of the obstruction (as previously described), in 38 patients (73 per cent) and ineffective in 14 (27 per cent). In 35 patients (67 per cent) thrombolysis was judged to have conferred unique benefit since an underlying correctable lesion was demonstrated and corrective therapy was effective.

Mortality

Over the 4-year period 18 patients (35 per cent) died, seven (13 per cent) within the first 30 days (*Table 1*). Analysis of the cause and timing of death showed that in only three cases could mortality be attributed directly to unrelieved limb ischaemia and that these deaths occurred within the first 30 days. The cause and time of late death are shown in *Table 2*. The majority of patients in whom lysis was effective survived with limb

salvage to die from another cause at a later date. There were no deaths attributable to stroke, haemorrhage or other complication of thrombolysis.

Amputation

Eleven patients underwent amputation: six (12 per cent) had surgery within 30 days and five (10 per cent) at a later time. Of these five, there was evidence of progression of distal disease in three (who underwent amputation at 3 months, 3 months and 2 years 8 months respectively) and of unrelieved microembolic occlusion caused by popliteal artery aneurysm in two (who underwent amputation at 11 months and 1 year 9 months respectively). In these last two patients distal amputation was required despite successful proximal bypass.

Further interventions

These are shown in *Tables 3* and *4*. Complications of the treatment were divided into major and minor, as previously, and there were two complications of angioplasty following thrombolysis.

Major complications

One patient developed temporary diplopia and ptosis associated with a parieto-occipital haematoma proven on computed tomography. The patient made a full recovery. A second patient sustained superficial femoral artery perforation after successful lysis. This was repaired with a vein patch.

Minor complications

These consisted of two allergic reactions, one acute confusional state, one large groin haematoma with abscess formation and a second large groin haematoma, which produced local pressure thought to be responsible for a proven deep vein thrombosis.

Complications of angioplasty after thrombolysis

One patient had thrombosis of a reversed saphenous vein graft and, after successful lysis, had the graft ruptured during attempted dilatation of a stricture in its upper third. The graft was replaced by a synthetic conduit which also failed and the patient came to amputation. There was one case of embolization of atheromatous debris following angioplasty; this produced no lasting clinical effects. No deaths or amputations could be attributed directly to a complication of therapy. The diagnosis of the cause of the occlusion made after thrombolysis is shown in *Table 5*.

Discussion

Changing patterns of acute limb ischaemia

Episodes of enthusiasm and disappointment have marked the development of thrombolysis[5] over the past 30 years. Postangioplasty thrombosis, and new thrombolytic drugs and techniques of administration have led to a resurgence of interest. This is particularly so in the difficult problem of acute limb ischaemia, the ideal management of which has yet to be agreed. Significant benefit accrues simply by efficient medical care and anticoagulation therapy, but the additional benefits from surgery, interventional radiology, thrombolysis – or all methods in combination – have not been measured. The decline in the incidence of rheumatic heart disease and systemic embolism in younger patients during the past two decades has been balanced by a significant increase in the number of elderly patients at risk from atherosclerosis and arterial thrombosis. The pathology and outcome for patients with systemic embolism are substantially different from those of patients with native artery thrombosis[5]. The risk of systemic embolism is to life rather than limb (mortality rate 17 per cent, amputation rate 13 per cent), whereas for intra-arterial thrombosis the mortality rate is less (9 per cent) but the amputation rate higher (28 per cent). These figures represent short-term results (within 30 days) and seriously underestimate the threat to the untreated limb after arterial thrombosis. The classical acute white leg resulting from cardiac embolism is now rare and the majority of patients presenting with an ischaemic limb suffer from spontaneous arterial thrombosis, thrombosis following an interventional radiological procedure, or failure of an arterial graft.

The fundamental question is whether the results of thrombolysis in acute ischaemia are now superior to those of the simpler management of medical support, heparin and elective investigation. Positive evidence for the effectiveness and safety of elective surgical management in the USA has been presented[6] but in Guildford elderly patients predominate, many of whom are high-risk women[1] with end-stage disease; direct comparison is difficult. The present authors have responded to current uncertainty about the best management by an early study of low-dose intra-arterial streptokinase and in 1985 published the first account in the UK of this therapy for acute lower-limb ischaemia[4]. From that experience, a single treatment protocol was defined[3]. The management depends on the personal involvement of the same vascular surgeon and interventional radiologist who also carry out all the interventional procedures. The present paper records that experience and is unique in that all patients treated suffered acute ischaemia and all have been studied prospectively for at least 4 years.

Advantages of low-dose intra-arterial infusion

Earlier reports of thrombolysis using systemic streptokinase at high dosage and for long periods showed effective dissolution of clot but a prohibitive risk of haemorrhage and stroke. Modern imaging techniques and catheters have for a decade made the local intra-arterial route the approach of choice. Lower doses and shorter infusion times have reduced complications while permitting precise monitoring of effect by repeat arteriography. New agents, including tissue plasminogen activator (tPA) and urokinase, have been used; both high- and low-dose regimens have been recommended[7,8]. Sometimes these are supplemented by mechanical disruption and clot suction, and in some hospitals all these methods have been tried. Having established a protocol that appeared to be reasonably safe and inexpensive, and one that could be managed conveniently within the limited facilities of a district general hospital, the authors have deliberately chosen to continue with low-dose intra-arterial infusion of streptokinase in all patients in whom allergy or recent exposure did not contraindicate its use. Patients sensitized to streptokinase are in our experience still rare. The alternative of low-dose intra-arterial tPA has been required in fewer than 5 per cent of patients, none of whom is included in this series. The more widespread use of streptokinase for myocardial infarction may change this ratio by increasing the incidence of allergy, but the improved purity of modern streptokinase and its low cost are significant advantages. Recent evidence suggesting that it may be as effective as tPA and also have enhanced safety[9,10] makes the authors reluctant to use the more expensive agent as a first choice.

Urokinase, while commonly used in the USA[11], is very expensive and has no specific advantage with respect to lysis itself, although it does offer protection against allergic reaction. The authors' experience with streptokinase has shown that low-dose infusion for a period of 24–36 h yields greatest benefit with minimal risk and this series is the largest and longest so far reported using a single protocol. Other centres, particularly regional vascular units with larger numbers to treat, have made valuable contributions to the understanding of the effects of different drugs, dosages and methods of administration[12,13] but practice varies widely throughout the country[14] and direct comparison with the present work is difficult. In acute ischaemia, streptokinase and tPA have similar rates of lysis and complications[15]. It has been suggested that tPA may be superior to streptokinase because of more rapid lysis[16] but that evidence must be viewed cautiously, bearing in mind the prolonged and perhaps ineffective lysis experienced by these authors using streptokinase early in their series. The present authors have previously identified prolonged and ineffective infusion as significant risk factors for haemorrhage and failure. With increasing experience, lysis times tend to fall and the risks of haemorrhage, stroke and failure are thereby reduced.

The effectiveness of an infusion in removing clot has been described in terms of complete or partial lysis. It is well to remember that radiological distinction between persisting clot and atheroma is imprecise, and that some failures of lysis are certainly caused by atheromatous debris that requires surgical removal. It should also not be forgotten that some patients in whom lysis is effective will none the less lose their limb or die; successful lysis does not necessarily mean a successful clinical result.

Appreciating the hazards of prolonged infusion, many recent reports[17] have favoured a higher dose bolus technique using streptokinase or tPA, while observing the effects directly over periods of 30–60 min. The effect is often dramatic; it may extend the repertoire of thrombolysis to patients with even more acute and severe ischaemia, and may allow immediate intervention for clot suction and angioplasty. This may be a particularly useful method where dedicated radiological facilities are constantly available and there is clinical urgency, but the safety of high-dose bolus regimens has yet to be established. The present authors are reluctant to change their protocol in any way that might increase the risk of stroke. While there may be a role for a single higher dose bolus when the catheter is first positioned, to check that lysis is possible and thereby avoid the 12-h low-dose trial infusion, the safety of high-dose treatment must be proved. We believe that low-dose intra-arterial streptokinase infusion with check radiographs every 12 h offers the advantages of proven safety, organizational convenience and economy.

What other measures are required?

Throughout the authors' experience thrombolysis has been regarded mainly as a valuable diagnostic aid, which may sometimes provide a complete treatment but more usually will reveal an underlying cause that then requires angioplasty or surgical correction. They have found that thrombolysis alone is sufficient in fewer than 20 per cent of patients.

Assessment of long-term results

The ultimate question to be asked of any medical intervention is whether it improves the length and quality of life at reasonable cost. Reporting mortality and amputation rates at 30 days is inadequate, but there are very few accounts in which later outcome is recorded. In some studies, results are confused by the mixture of acute, subacute and chronic ischaemia[18] and in some by uncertainty about the severity of lesions treated[19,20]. Some reports of surgical results do not define primary and secondary patency[21].

Comparison of outcome in patients with high risk is difficult because the rate of attrition of those with critical ischaemia is high. At 5 years only 40 per cent will survive, compared with 70 per cent of those with claudication[22]. Life-table analysis suggests objectivity[23] but may be inappropriate, since death in patients with peripheral vascular disease is usually from causes other than the peripheral ischaemia that is being assessed. Similarly, it is of little value to report 'patency rates' that have not been proved by repeat arteriography, since it is known that reocclusion can occur without clinical deterioration. Surrogate indicators such as limb salvage should not be used to indicate patency of a treated vessel. The durability of any intervention requires unambiguous proof by arteriography or duplex ultrasonography before patency can be claimed. This study, therefore, reports only the definite endpoints of death and amputation.

Need for controlled clinical trials

Randomized controlled trials are urgently needed since current reports include patients of widely differing degrees and duration of ischaemia, and results from centres where surgery may be the preferred or only option. Some studies of thrombolysis have excluded patients presenting within 24 or 48 h of the onset of ischaemia, all of whom were diverted to surgical care.

In Guildford all patients except those with acute white leg have been considered for thrombolysis. It is concluded that thrombolysis offers the prospect of saving the acutely ischaemic limb of the elderly arteriopathic patient until probable death from another cardiovascular cause; an evaluation of exactly when it is the most effective treatment now needs to be made.

Low-dose aspirin fails to inhibit increased platelet reactivity in patients with peripheral vascular disease

T. K. Walters, D. C. Mitchell and R. F. M. Wood

Professorial Surgical Unit, St Bartholomew's Hospital, London EC1E 7BE, UK

Correspondence to:
Miss T. K. Walters

A study was performed to evaluate the effect of low-dose aspirin (75 mg/day) on platelet reactivity in patients with peripheral vascular disease. Platelet function was measured in 31 patients with advanced peripheral vascular disease requiring surgery. Shear-induced haemostasis and collagen-induced thrombus formation were used as indicators of platelet reactivity. They were measured in non-anticoagulated fresh whole blood samples ex vivo *using a haemostatometer. Results were compared with those from 30 age- and sex-matched controls. Shear-induced haemostasis and collagen-induced thrombus formation were also measured in 18 of the 31 patients before the start of aspirin administration (before operation) and 1 week after surgery. Patients with advanced peripheral vascular disease were found to have increased platelet reactivity with a mean(s.e.m.) shear-induced haemostasis index of 1977(180) mmHg s compared with a control value of 3161(234) mmHg s ($P < 0{\cdot}001$) and a mean(s.e.m.) collagen-induced thrombus formation index of 3980(460) mmHg s compared with a control value of 5350(420) mmHg s ($P = 0{\cdot}02$). Perioperative low-dose aspirin failed to inhibit platelet function in patients with peripheral vascular disease.*

Platelets are thought to play a pivotal role in the pathogenesis of human atherosclerosis[1] and in restenosis after vascular surgery or angioplasty. Antiplatelet agents have been shown to protect against stroke[2] and adverse cardiovascular events[3]. Aspirin is one of the most extensively studied of these agents and it may play an important role in modifying responses to the insertion of vascular grafts[4,5] or to balloon angioplasty[6,7]. However, the data remain confusing, with a recent study showing protective effects of aspirin in the coronary and cerebral circulations, but not in peripheral vein bypass grafts[8].

Aspirin has been shown to reduce smooth muscle cell proliferation in an animal model[9]. The mechanism is thought to involve the inhibition of platelet activation and degranulation. It is used by vascular surgeons in the management of peripheral vascular disease, but the rationale for its use is not well defined and dosage regimens are arbitrary. This study was undertaken to examine the effect of a single-dosage regimen of aspirin at 75 mg/day. This dose was chosen as it is that given to patients in this unit after angioplasty[10].

Patients and methods

Study population

Thirty-one symptomatic patients with peripheral vascular disease were studied before they took any aspirin. Eighteen of this group underwent a procedure to treat peripheral vascular disease after starting aspirin 75 mg/day on the night before surgery. They were also studied a second time 1 week after the procedure. The only other drug used in this study was heparin, which was given during (5000 units) and after (5000 units subcutaneously twice daily) operation until the patient was mobile. No patient was given heparin for more than 4 days and repeat platelet studies were carried out at least 7 days after surgery. The patient group was compared with an age- and sex-matched population of 30 controls (*Table 1*). The controls were not diabetic, had no history of heart disease or claudication and had a palpable dorsalis pedis pulse.

Measurement technique: haemostatometry

Blood was taken from an uncuffed vein into a syringe and measurements obtained immediately on fresh non-anticoagulated samples. Shear-induced haemostasis and collagen-induced thrombus formation were measured using a haemostatometer. These methods have been described and validated in relation to the pathogenesis of coronary thrombosis[11,12]. The coefficients of variation of repeated measurement of shear-induced haemostasis and collagen-induced thrombus formation over a 2-year period in a single individual were 14 and 8 per cent respectively.

Shear-induced haemostasis. The release of adenosine 5′-diphosphate from platelets and red blood cells, and the generation of thrombin, are the major mediators of the shear-induced platelet aggregation that follows breach of a blood vessel wall. Shear-induced haemostasis was measured by producing a standard 'bleeding' stimulus in a polyethylene tube. Immediately after venesection, non-anticoagulated blood was perfused through polyethylene tubing at a constant pressure of 60 mmHg. Once a steady state was achieved, which took less than 2 min, a hole of known dimension was punched in the tube with a fine needle. This resulted in 'bleeding' into a surrounding bath of oil. The blood loss led to a rapid decrease in pressure in the system. As platelets plugged the hole, the pressure in the system recovered and was continuously monitored. The recovery phases have been well characterized[13] and can be used as a measure of platelet reactivity in response to a standard initial shear stress, calculated to be 32 N/m². Reactivity was measured as an integral of change in pressure against time. The faster the pressure rise, the smaller the number generated and the more reactive the platelets (*Figure 1*).

Table 1 *Comparison of the patient group with age- and sex-matched controls*

	Mean(s.e.m.) age (years)	Sex ratio (M:F)
Controls ($n = 30$)	64·6(1·7)	21:9
Patients ($n = 31$)	67·6(1·6)	23:8

Presented in part to the Surgical Research Society in Lancaster, UK, July 1991 and published in part in abstract form as Br J Surg *1991;* **78***: 1489*

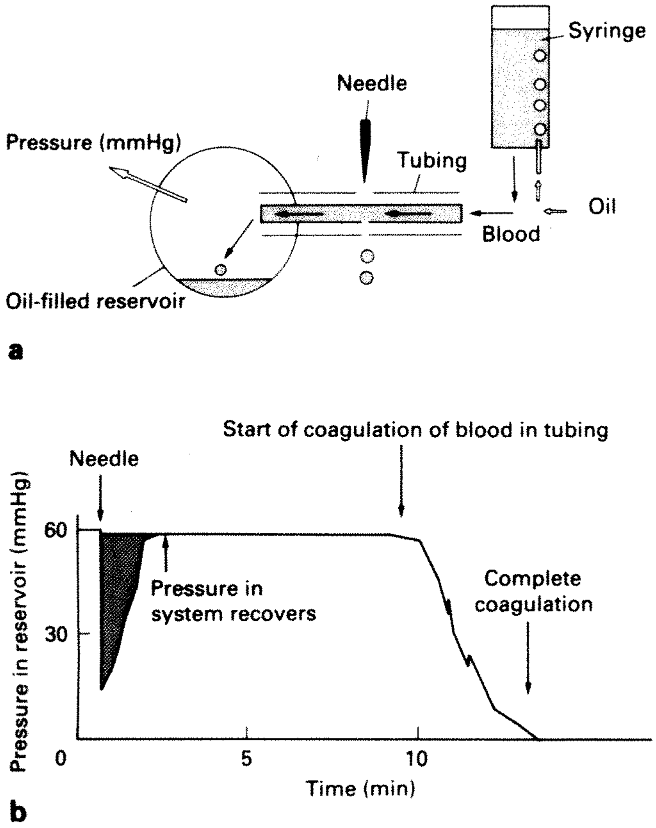

Figure 1 **a** *Schematic diagram of the shear-induced haemostasis test. Blood is perfused through polyethylene tubing from a syringe into an oil-filled reservoir. The tubing is pierced with a needle to induce 'bleeding' and haemostatic platelet plug formation in the holes. The reaction is monitored by pressure changes measured distally in the reservoir.* **b** *Changes in pressure with time in shear-induced haemostasis. The initial pressure is 60 mmHg. This falls sharply following needle puncture of the tubing and 'bleeding' through the holes. As platelet plugs are formed, the pressure recovers to its original value and flow of blood is restored in the tubing. The speed at which this occurs gives a measurement of the platelet reactivity in response to shear stress. Subsequently the pressure falls again as a result of complete coagulation of the blood in the tubing. The shaded area gives an index of platelet reactivity due to shear stress, expressed as an integral of pressure with time. The lower the value, the more reactive the platelets*

Collagen-induced thrombus formation. A second sample of blood was perfused through an identical piece of polyethylene tubing, which contained a standard length of catgut within its lumen. The pressure in the tubing was measured at a point distal to the collagen. As a platelet plug formed on the catgut and occluded the lumen, the measured pressure fell. This change in pressure was continuously monitored. Reactivity was measured as an integral of pressure change with time; as for shear-induced haemostasis, the more reactive the platelets, the smaller the measurement obtained (*Figure 2*).

Statistical analysis

Values are expressed as mean(s.e.m.). Statistical analysis for differences between groups was performed using Student's *t* test. For differences between preoperative and postoperative measurements a paired *t* test was used.

Results

Shear-induced haemostasis and collagen-induced thrombus formation in blood samples from patients with peripheral vascular disease and age-matched controls are shown in *Figure 3*. Patients with peripheral vascular disease had significantly more reactive platelets than controls as measured by both haemostatometer tests. After surgery, in the subgroup of 18 patients, aspirin 75 mg/day failed to reduce platelet reactivity (*Figure 4*). Although there was a trend indicating that platelets were more reactive after operation, this was not statistically significant.

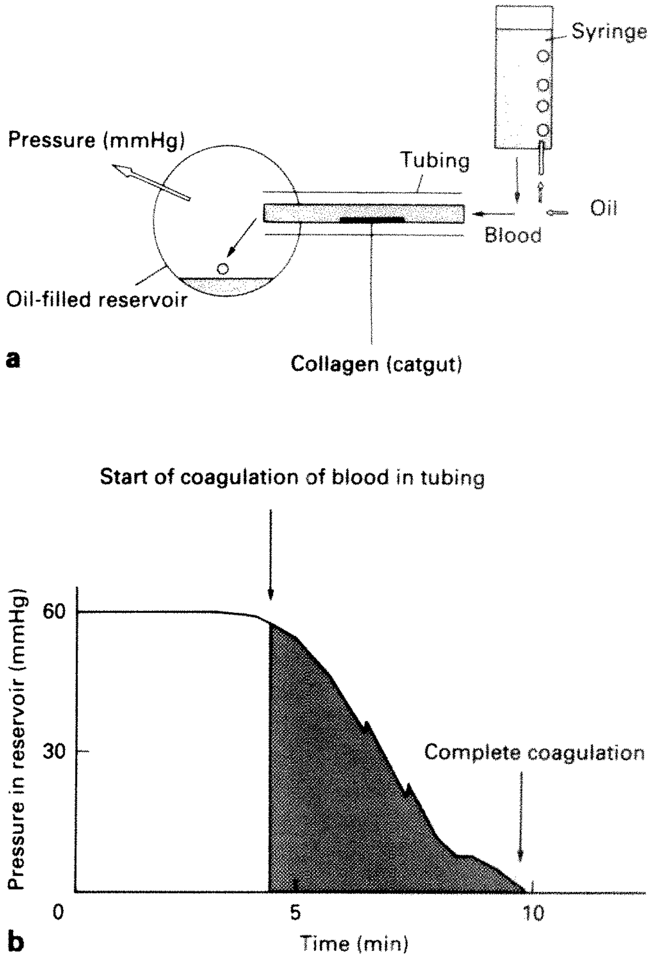

Figure 2 **a** *Schematic diagram of the collagen-induced thrombus formation test. Blood is perfused through polyethylene tubing from a syringe into an oil-filled reservoir. The tubing contains a standard sized piece of catgut. Platelets adhere to the catgut and block the tubing. The reaction is monitored by pressure changes measured distally in the reservoir.* **b** *Changes in pressure with time in collagen-induced thrombus formation. The initial pressure is 60 mmHg; as platelets adhere to the catgut and occlude the tubing, the pressure measured distally falls. The speed at which this occurs gives a measurement of the platelet reactivity in response to collagen-induced thrombus formation. The shaded area gives an index of platelet reactivity due to collagen-induced thrombus formation. The lower the value, the more reactive the platelets*

Patients* (n = *18*) *received aspirin 75 mg/day. No change was found in platelet reactivity after administration of low-dose aspirin* (*75 mg/day*) *for 1 week*

Discussion

This study shows that patients with peripheral vascular disease have more reactive platelets than an age- and sex-matched population. This is similar to the prothrombotic tendency previously found in atherosclerotic patients after myocardial infarction[14] and in those studied 3 months following coronary artery bypass grafting[13].

The interaction of platelets with the damaged vessel wall makes a significant contribution to thrombus formation[15,16]. Release of growth factors[17] stimulates smooth muscle cell migration[18] and contributes to the myointimal hyperplasia[19] that follows percutaneous transluminal angioplasty and bypass grafting. Platelets are activated by changes in shear stress within the vessel after bypass, or by exposure of collagen in the subendothelium following the splitting of atherosclerotic plaque by angioplasty[15]. Agents that decrease platelet responses to abnormal shear forces and exposed collagen should decrease thrombus generation and reduce subsequent smooth muscle cell proliferation generated by the release of platelet mitogens. Aspirin is a potent inhibitor of platelets, with demonstrable effects on the cardiac and cerebral circulations in low doses. Its propensity to cause gastrointestinal side-effects, particularly in the elderly, led to use of a low dose (75 mg/day) in patients undergoing angioplasty in this unit. This study establishes that this dosage has no significant effect on platelet reactivity and we advise against the use of such a low dose.

The thrombotic status of patients (n = 294) taking aspirin 75 mg/day 3 months after coronary artery bypass surgery has previously been reported[13]. Ninety of these patients had significantly enhanced platelet reactivity and were advised to increase the daily aspirin dose from 75 to 300 mg. When they were retested 1 month later, it was found that raising the daily dose of aspirin significantly increased the antiplatelet effect measured by the shear-induced haemostasis test[13] (*Figure 5*). We recommend that aspirin be given in a dose of 300 mg/day to patients undergoing peripheral vascular surgery or angioplasty. Whether a correlation between platelet reactivity and subsequent restenosis can be established remains to be determined.

Over a 17-year period, 2930 vascular procedures were performed for chronic lower-limb occlusive disease. During this time, the total vascular surgical workload rose significantly as a result of an increase in the rates of arterial reconstruction and percutaneous transluminal angioplasty. Although the major lower-limb amputation rate did not change significantly, there was a decrease in the above- to below-knee ratio. In addition, there were significant increases in the percentage of patients treated over the age of 75 years and the proportion of attempted revascularizations before amputation. The mortality rates for arterial reconstruction, percutaneous transluminal angioplasty and amputation did not change significantly during the study period. The duration of hospital stay increased significantly for patients undergoing amputation and decreased significantly for those receiving arterial reconstruction.

The treatment of lower-limb ischaemia secondary to occlusive arterial disease represents a major part of the workload of vascular surgeons in the UK. During the past two decades, the treatment options available for these patients have increased dramatically. Reconstructive vascular surgery has become widely established as a result of advances in preoperative assessment, anaesthesia, surgical technique and postoperative care that have developed alongside rapid progress in design and manufacture of prosthetic grafts. A major advance occurred in the late 1970s with the introduction of percutaneous transluminal angioplasty (PTA)[1,2], which has become widely established for the treatment of peripheral vascular disease. The indications for surgical and/or radiological intervention in patients with lower-limb occlusive arterial disease have widened with the advent of these new techniques. This paper assesses the changing trends in the management of lower-limb ischaemia in a district health authority over the 17-year period 1974–1990.

Patients and methods

There are three hospitals in the Leicestershire Health Authority that provide vascular services: Leicester Royal Infirmary, Leicester General and Glenfield General. Although vascular surgery was available in Leicester before 1974, it developed rapidly from 1974 onwards following the opening of Leicester Medical School and the University Department of Surgery. At present, vascular services in Leicester are provided by four surgeons: two at the Royal Infirmary, and one each at Leicester General and Glenfield General. PTA was introduced in 1982 and is now available at all three hospitals. The population of Leicester during the period of the present study increased from 829 100 in 1974 to 897 700 in 1990.

The data for this study were obtained from the Hospital Activities Analysis database of the Leicestershire Health Authority from 1974 to 1987 and the Trent Regional Information System from 1987 to 1990. Data were complete for each year except between September 1986 and April 1987 for which no data were available. The two databases contain information on all patients discharged from the hospitals that serve the Leicestershire Health Authority, and each patient is coded according to diagnosis and treatment. The diagnosis codes are based on the International Classification of Diseases, ninth revision, clinical modification (ICD-9-CM) and the treatment codes are based on the Office of Population Censuses and Surveys (OPCS) classification of surgical operations, second, third and fourth revisions. The databases provide information on patient name, age, sex, length of hospital stay, discharge and mortality.

Using the two databases, OPCS treatment codes and ICD codes, discharge information was obtained on all patients with chronic occlusive peripheral vascular disease who underwent lower-limb arterial reconstruction (including abdominal aortic procedures), PTA of the lower-limb vessels or major lower-limb amputation (above- or below-knee) between 1974 and 1990. Initially the OPCS treatment codes were used to identify all patients who underwent lower-limb vascular reconstruction (including abdominal procedures), angioplasty or amputation. The search-profile criteria are shown in *Table 1*. To include only patients with chronic lower-limb occlusive disease, those who did not have the ICD codes shown in *Table 2* were excluded. In addition, patients with venous, lymphatic, inflammatory, soft tissue and bone disorders were excluded, as were those with arterial trauma or aneurysmal disease who had the ICD codes shown in *Table 3*.

Data validation

To check the accuracy of the Hospital Activities Analysis data and their usefulness for identification of patients with chronic lower-limb occlusive peripheral vascular disease, the 1990 discharges from the Leicester Royal Infirmary identified by the Hospital Activities Analysis

data were compared with those identified by the Royal Infirmary vascular audit. The overall accuracy of the Hospital Activities Analysis data was 80 per cent.

Statistical analysis

To standardize the data in terms of age and sex for the three procedures, the number of vascular reconstructions and amputations for the years 1974–1990 inclusive, and the number of angioplasties for the years 1982–1990 inclusive were arranged into quinary bands for age and sex for each year. For the years 1986 and 1987, data were for 8 months of the year rather than the full year. It was assumed that there were no seasonal effects on the number of procedures, and the figures for these years were multiplied by 1·5 to produce estimated rates for the full calendar year. The rates of the procedures for each year were calculated by using the mid-year estimated resident population for Leicestershire, for the relevant year, as the denominator. Adjustments for age and sex were made by direct standardization using the 1981 census figures for Leicestershire for people aged 20 years and over as the standard population. Differences in the rates of variables with time were analysed by linear regression with year as the independent variable and rate as the dependent variable. In addition, continuous variables were analysed using the Mann–Whitney *U* test and discrete variables with the χ^2 test.

Results

During the 17-year period from 1974 to 1990, 2930 vascular procedures were performed for chronic occlusive disease of the lower limb: 1095 arterial reconstructions, 677 PTAs and 1158 major lower-limb amputations.

Standardized rates of procedures

The total vascular workload and the standardized rates of arterial reconstruction, PTA and amputation are shown in *Figures 1–4*. All data are fitted with linear regression lines. The rate of all procedures (*Figure 1*), which represents the total vascular workload in Leicestershire, has increased significantly over the study period ($r^2 = 0{\cdot}72$, $P < 0{\cdot}001$). Similarly, the rates of arterial reconstruction (*Figure 2*) and PTA (*Figure 3*) have also increased significantly ($r^2 = 0{\cdot}89$, $P < 0{\cdot}001$ and $r^2 = 0{\cdot}59$, $P < 0{\cdot}001$ respectively). The rate of major lower-limb amputation (*Figure 4*) has fallen but this decrease is not statistically significant ($r^2 = 0{\cdot}09$, $P = 0{\cdot}25$).

Above- to below-knee amputation ratio

Although the total amputation rate did not fall significantly over the 17-year period, there was a change in the level of amputation. The ratio of above- to below-knee amputations is shown in *Figure 5*; this demonstrates a significant fall over the study period ($r^2 = 0{\cdot}51$, $P = 0{\cdot}001$).

Patients undergoing attempted revascularization before amputation

The percentage of attempted arterial reconstructions or PTAs before major lower-limb amputation was performed at the same hospital admission is shown in *Figure 6*. There has been a significant increase in the number of attempted revascularizations before amputation ($r^2 = 0{\cdot}75$, $P < 0{\cdot}001$). The number

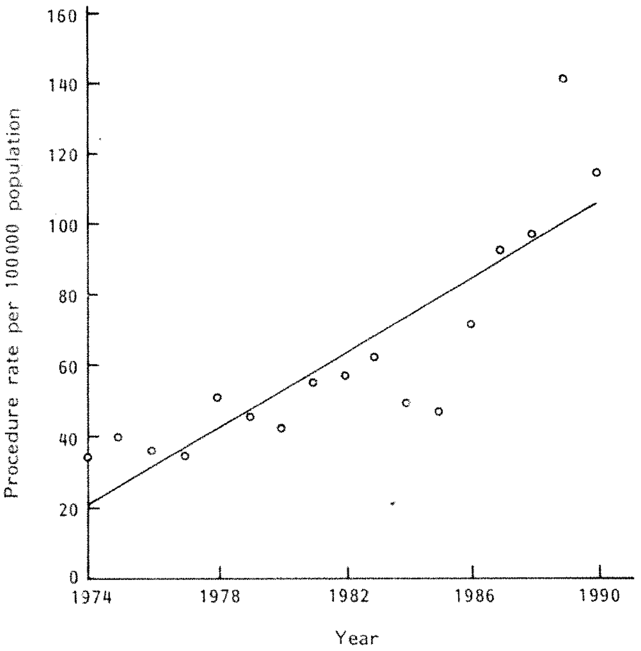

Figure 1 *Total vascular workload for lower-limb ischaemia. Data are presented as age- and sex-standardized rates for all procedures (arterial reconstruction, percutaneous transluminal angioplasty and major lower-limb amputation) per 100 000 population of Leicestershire* ($r^2 = 0{\cdot}72$, $P < 0{\cdot}001$). *Points are fitted with the best-fit linear regression line*

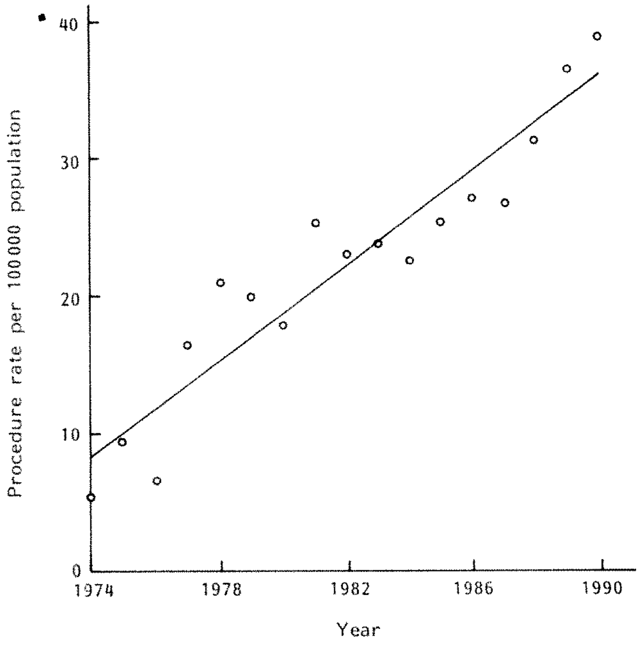

Figure 2 *Arterial reconstruction for lower-limb ischaemia. Data are presented as age- and sex-standardized rates for arterial reconstruction per 100 000 population of Leicestershire* ($r^2 = 0{\cdot}89$, $P < 0{\cdot}001$). *Points are fitted with the best-fit linear regression line*

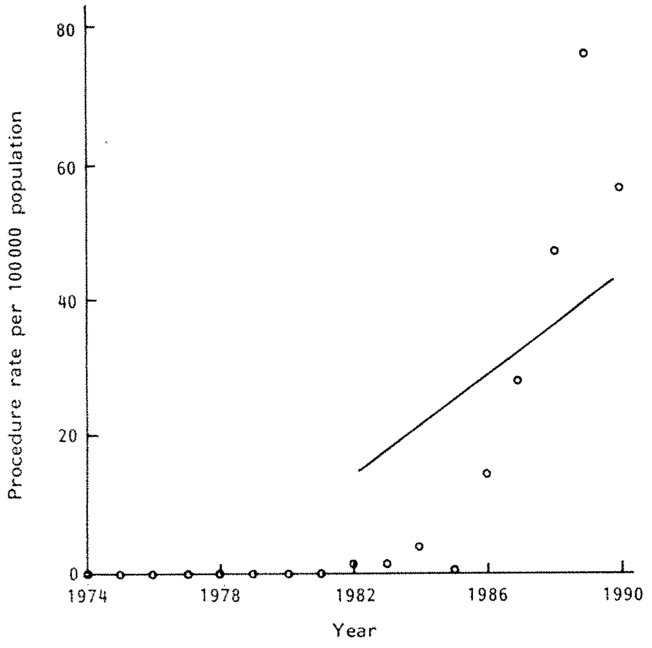

Figure 3 *Percutaneous transluminal angioplasty (PTA) for lower-limb ischaemia. Data are presented as age- and sex-standardized rates for PTA per 100 000 population of Leicestershire ($r^2 = 0.59$, $P < 0.001$). Points are fitted with the best-fit linear regression line*

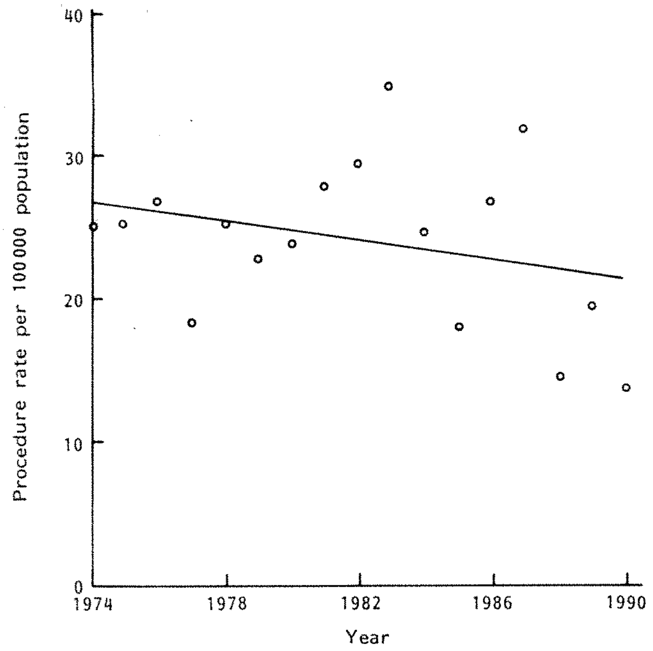

Figure 4 *Major amputation for lower-limb ischaemia. Data are presented as age- and sex-standardized rates for amputation per 100 000 population of Leicestershire ($r^2 = 0.09$, $P = 0.25$). Points are fitted with the best-fit linear regression line*

of reconstructions and PTAs performed before amputation for each year is shown in *Table 4*. Despite the rapid increase in the number of PTAs performed overall, surgical reconstruction remains the preferred treatment option in limb-threatening ischaemia.

Treatment of patients with diabetes mellitus

The methods of treatment of diabetic and non-diabetic patients over the 17-year period are illustrated in *Figure 7*. Overall, 58 per cent of diabetic patients underwent major lower-limb amputation compared with 33 per cent of non-diabetics ($\chi^2 = 143.7$, 1 d.f., $P < 0.001$).

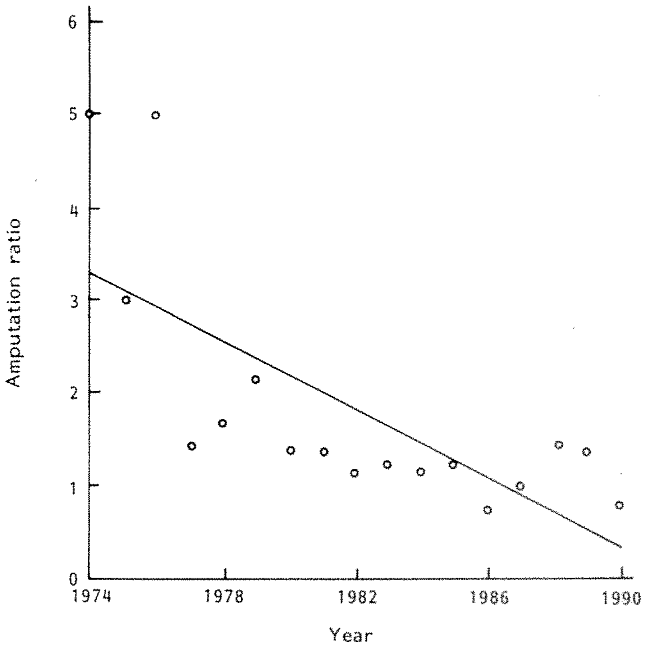

Figure 5 *Change in above- to below-knee amputation ratio over the study period ($r^2 = 0.51$, $P = 0.001$). Points are fitted with the best-fit linear regression line*

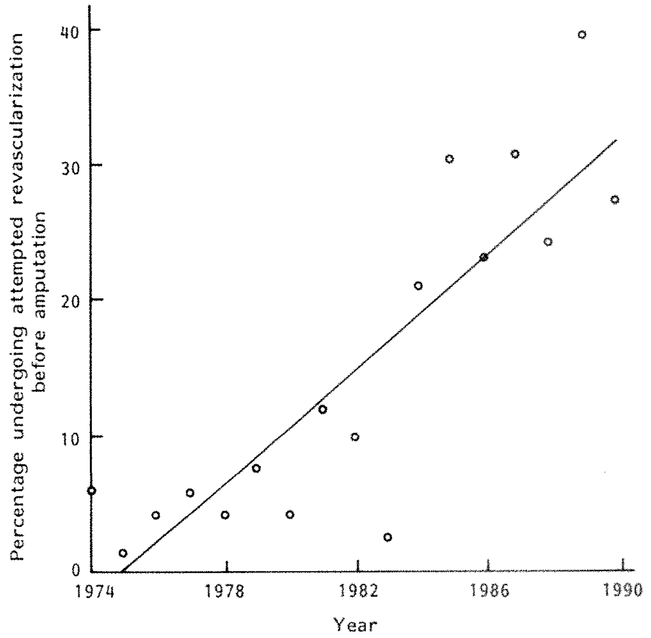

Figure 6 *Percentage of patients per year who underwent attempted revascularization (arterial reconstruction and/or percutaneous transluminal angioplasty) before amputation ($r^2 = 0.75$, $P < 0.001$). Points are fitted with the best-fit linear regression line*

Proportion of elderly patients treated

The percentage of patients over the age of 75 years who underwent either arterial reconstruction, PTA or major lower-limb amputation is shown in *Figure 8*. There was a significant increase in the number of elderly patients who underwent reconstruction or PTA ($r^2 = 0.75$, $P < 0.001$ and $r^2 = 0.58$, $P < 0.001$ respectively). The percentage of patients over the age of 75 years who underwent major amputation also increased during the study period but this increase was not statistically significant ($r^2 = 0.18$, $P = 0.09$).

Duration of hospital stay

The duration of hospital stay for patients undergoing arterial reconstruction or amputation is shown in *Figure 9*. There has

	Reconstruction		Percutaneous transluminal angioplasty		Amputation	
Year	Total no.	No. of deaths	Total no.	No. of deaths	Total no.	No. of deaths
1974	15	2 (13)	0	0 (0)	66	13 (20)
1975	27	0 (0)	0	0 (0)	68	19 (28)
1976	19	3 (16)	0	0 (0)	72	11 (15)
1977	47	3 (6)	0	0 (0)	51	7 (14)
1978	60	1 (2)	0	0 (0)	72	9 (12)
1979	58	4 (7)	0	0 (0)	66	16 (24)
1980	52	8 (15)	0	0 (0)	69	19 (28)
1981	75	6 (8)	0	0 (0)	83	24 (29)
1982	69	4 (6)	5	0 (0)	89	15 (17)
1983	71	8 (11)	5	0 (0)	105	31 (30)
1984	69	4 (6)	12	0 (0)	76	20 (26)
1985	78	15 (19)	2	1 (50)	56	14 (25)
1986	56	7 (12)	29	2 (7)	56	11 (20)
1987	55	6 (11)	57	1 (2)	68	18 (26)
1988	98	11 (11)	146	6 (4)	49	16 (33)
1989	119	13 (11)	240	7 (3)	63	20 (32)
1990	127	11 (9)	181	3 (2)	47	8 (17)

Values in parentheses are percentages

been a significant increase in the duration of hospital stay after amputation ($r^2 = 0.25$, $P = 0.04$) and a significant decrease in the duration of hospital stay after reconstruction ($r^2 = 0.42$, $P = 0.005$).

Mortality

The mortality rate expressed as percentage deaths per procedure per year is shown in *Table 5*. Analysis by linear regression revealed that the mortality rate associated with each procedure has not changed significantly during the study period (reconstruction: $r^2 = 0.06$, $P = 0.35$; PTA: $r^2 = 0.06$, $P = 0.33$; amputation: $r^2 = 0.15$, $P = 0.13$).

Discussion

The most significant finding in this study is the dramatic rise in the vascular workload as a result of an increase in the rates of arterial reconstruction and PTA between 1974 and 1990. This in turn is due mainly to expanded indications for intervention in lower-limb ischaemia. It is also likely that advances in other fields of medicine have resulted in more elderly patients presenting with peripheral vascular disease rather than dying from other causes, despite the static prevalence of peripheral vascular disease in the elderly population[3,4]. It is also possible that peripheral vascular disease is being diagnosed more often by clinicians, with subsequent referral of patients for treatment; increasing numbers of repeat procedures are also being performed[5].

The major lower-limb amputation rate has not fallen significantly during the period of this study. Again, this may be because the number of elderly patients presenting with limb-threatening ischaemia is increasing. Although we have no direct evidence of this, there has been a significant increase in the proportion of patients over 75 years old undergoing revascularization. In addition, distal bypass surgery for limb-threatening ischaemia has been performed in Leicester from 1982 onwards[6]; since then, approximately 10 per cent of patients per year undergoing femorodistal bypass have been referred from outside Leicestershire. This commitment to distal vascular reconstruction for critical leg ischaemia[7] is reflected by the increase in the percentage of attempted revascularizations performed before amputation. In this study, there were significantly more amputations in diabetics, which confirms reports from other authors[8,9].

Several previous studies have investigated the effects of modern vascular services on amputation rates and have produced conflicting results. In 1986, Anderson *et al.*[10] found that PTA did not affect the number of reconstructions or amputations performed for peripheral vascular disease, whereas Jeans *et al.*[11] reported that the introduction of PTA was accompanied by an increase in the number of reconstructions and a fall in the number of amputations. In a larger study from the USA, Veith *et al.*[12] demonstrated that an aggressive policy of vascular intervention in the form of PTA and reconstructive surgery was accompanied by a fall in amputation rate. However, all of these studies were from single centres and some contained small numbers or selected subsets of patients; the data were not age- and sex-standardized. In contrast, Tunis *et al.*[5] recently reported an age- and sex-standardized population-based study of 30 000 patients with peripheral vascular disease from Maryland, USA; they found that amputation rates remained static. These findings have been supported by results of other population-based studies[13,14]. Despite the static amputation rate, there has been a significant fall in the ratio of above- to below-knee amputations. This is due to greater awareness that patients undergoing below-knee amputation have a better chance of walking again[15]. There is some evidence now to suggest that failed distal vascular reconstruction does not jeopardize amputation level[16].

There has not been a significant change in the mortality rate associated with arterial reconstruction, PTA or amputation over the period of the present study. It might be expected that the proportionate increase in the number of elderly patients undergoing reconstruction would lead to a higher mortality rate, but this has probably been balanced by advances in anaesthesia and postoperative care. Such advances are also reflected in the decreased duration of hospital stay for patients undergoing arterial reconstruction. Unfortunately, this has been accompanied by an increase in the duration of hospital stay after amputation. The lack of rehabilitation beds locally for amputees may be a major factor in this increase.

In conclusion, there has been a dramatic increase in vascular surgical workload related to the treatment of chronic lower-limb ischaemia over the study period. The increasing demand for vascular surgical procedures has arisen mainly as a result of an increase in the elderly population.

Acknowledgements

The authors thank the vascular surgeons from Leicester and Glenfield General Hospitals for allowing inclusion of their patients in this study.

High-resolution ultrasonography was used to classify carotid plaques into five different types in 72 patients with symptoms and in 49 without, and with stenosis of the origin of the internal carotid artery > 70 per cent. There were 72 plaques in the symptomatic group and 75 in the asymptomatic group. Type 1 plaques were uniformly echolucent, type 2 predominantly echolucent, type 3 predominantly echogenic, type 4 uniformly echogenic and type 5 consisted of plaques that could not be classified owing to heavy calcification and acoustic shadows. Type 1 plaque was found in 90 per cent of patients with symptoms and in 10 per cent of those without, type 2 plaque was found in 53 and 47 per cent, type 3 in 34 and 66 per cent, and type 4 in 5 and 95 per cent, respectively. The preponderance of echolucent plaques in symptomatic patients with stenosis > 70 per cent supports the hypothesis that this type of plaque is unstable and tends to embolize. In contrast, in patients without symptoms there is preponderance of echogenic plaques.

High-resolution B-mode ultrasonography has the major advantage over arteriography that it can be used to characterize atherosclerotic plaques[1]. A classification that allows a closer study of the character and behaviour of plaques was introduced by Steffen *et al.*[2]. Four types of plaque were defined: type 1 is predominantly echolucent, type 2 substantially echolucent with small areas of echogenicity, type 3 predominantly echogenic with small areas of echolucency, and type 4 uniformly echogenic. In symptomatic arteries, irrespective of the degree of stenosis, types 1 and 2 predominate and correlate well with the presence of ulceration and haemorrhage. It has been shown that echolucent plaques have increased lipid and cholesterol levels, which makes them unstable and prone to ulceration and embolization. By contrast, echogenic plaques contain significantly more fibrin and collagen, giving them stability and rendering them less likely to embolize[3,4].

The European Carotid Surgery Trial[5] demonstrated an increased incidence of stroke in patients with transient ischaemic attacks (TIAs) and stenosis >70 per cent who were treated medically, and showed a significant reduction in ipsilateral hemispheric stroke following carotid endarterectomy. It is uncertain whether plaques producing stenosis > 70 per cent are unstable irrespective of echogenicity or whether the findings of Steffen *et al.* hold for this subgroup with severe stenosis.

The aim of this study was to test the hypothesis that, in the presence of stenosis of the internal carotid artery > 70 per cent, the ultrasonographic characteristics of plaques causing symptoms differ from those that do not. It has also been suggested that, with a reduction > 70 per cent in carotid lumen diameter, low flow may cause cerebral infarction or TIA; if this is true, there should be no relation between plaque type and symptoms[6].

Patients and methods

Seventy-two consecutive patients who underwent carotid endarterectomy and 49 who were found to have asymptomatic stenosis by duplex scanning were admitted into the study. The clinical presentation is shown in *Table 1*. All plaques in the symptomatic and asymptomatic groups caused stenosis >70 per cent as confirmed by duplex ultrasonography. In the patients with symptoms only the symptomatic side was assessed; in those without symptoms both sides were assessed. All scans were performed with an Ultramark 4 ATL scanner (Advanced Technology Laboratories, Letchworth, UK) with a 7·5-MHz high-resolution linear scan head. Scan settings (power output 50 per cent, dynamic range 47 dB, gain, gray scale, filters, ramp) were preset at machine start-up and were not altered during the examination. All patients were examined supine with slight head tilt. Anterior, lateral and posterior projections were used to image the plaque longitudinally. All images were recorded on photographic paper. Five types of plaque were defined:

1. Uniformly echolucent plaques. A thin echogenic cap at the margin of the plaque, as previously described by Steffen *et al.*[2], did not have to be visible. Diagnosis of stenosis could be made on the basis of the high-velocity waveform on duplex ultrasonography (*Figure 1*).
2. Predominantly echolucent plaques with <50 per cent echogenic areas (*Figure 2*).
3. Predominantly echogenic plaques with <50 per cent echolucent areas (*Figure 3*).
4. Uniformly echogenic plaques (*Figure 4*).
5. Plaques that could not be classified owing to heavy calcification and acoustic shadows.

Plaques were grouped into one of the above classes by two observers unaware of the presenting symptoms. The between-observer variation in determining the plaque type on the basis of the stated classification

	First observer					
	Type 1	Type 2	Type 3	Type 4	Type 5	Total
Second observer						
Type 1	20	1	0	0	0	21
Type 2	1	22	1	1	0	25
Type 3	1	4	9	0	0	14
Type 4	0	0	1	7	0	8
Type 5	0	0	0	0	2	2
Total	22	27	11	8	2	70

$\kappa = 0{\cdot}79$

Results

Table 2 shows good agreement on characterization of the carotid plaques into five different types by the two observers ($\kappa = 0{\cdot}79$). The total number of symptomatic plaques in the 72 patients with symptoms was 72 and in the 49 with no symptoms the total number of plaques was 75. Four carotid plaques (two symptomatic, two asymptomatic) could not be classified and were graded as type 5. They were excluded from the final analysis and are not included in *Tables 3* and *4*. The results in *Table 3* show a highly significant association between

Table 3 *Distribution of carotid plaques* of various types according to symptomatic status*

Type	Symptomatic	Asymptomatic
1 ($n = 30$)	27 (90)	3 (10)
2 ($n = 57$)	30 (53)	27 (47)
3 ($n = 35$)	12 (34)	23 (66)
4 ($n = 21$)	1 (5)	20 (95)

Values in parentheses are percentages. *Two symptomatic and two asymptomatic plaques that could not be classified are excluded

Table 4 *Distribution of carotid plaques of various types according to symptomatic status*

	Symptomatic	Asymptomatic
Types 1 and 2	57 (81)	30 (41)
Types 3 and 4	13 (19)	43 (59)
Total	70 (100)	73 (100)

Values in parentheses are percentages. $\chi^2 = 24{\cdot}40$, 1 d.f., $P < 0{\cdot}00001$

the type of plaque and symptoms ($\chi^2 = 39{\cdot}96$, 3 d.f., $P < 0{\cdot}000001$). There was also a highly significant linear trend in proportion to the number of patients with symptoms ($\chi^2 = 38{\cdot}84$, 1 d.f., $P < 0{\cdot}000001$) and no significant departure from a linear trend ($\chi^2 = 1{\cdot}12$, 2 d.f., $P > 0{\cdot}2$). *Tables 3* and *4* summarize the results. There was a predominance of echolucent plaques (types 1 and 2) in the symptomatic group and of echogenic plaques (types 3 and 4) in the asymptomatic group.

Discussion

The European Carotid Surgery Trial[5] has shown that, for symptomatic patients with carotid stenosis of 70–90 per cent, surgery results in a sixfold reduction in ipsilateral stroke. At 3 years after presentation and treatment, the total risk of surgical death, surgical stroke, ipsilateral ischaemic stroke or any other stroke was 12·3 per cent in the group undergoing surgery and 21·9 per cent in medically treated patients. It may be that a subgroup exists among those with stenosis >70 per cent that is at especially high risk of stroke; it may be possible to identify such a group by means of plaque characterization. Conversely, there may be a subgroup at low risk that might also be recognizable using duplex scanning of the plaque.

There is disagreement regarding the correct management of patients with asymptomatic carotid stenosis, and non-invasive imaging techniques have increased the number of asymptomatic lesions diagnosed, creating a dilemma for physicians. Although the overall risk of stroke in patients with asymptomatic stenosis is low, data from five studies suggest that there is a subgroup of patients with no symptoms and stenosis >75 per cent who are at increased risk of stroke[7–11].

Plaque morphology may be a more important factor in the pathogenesis of stroke than the degree of stenosis[12,13]. The composition of plaques from patients with symptoms is significantly different from that of plaques from those without. The former contain more total lipid and cholesterol, and less collagen and calcium[3]. A study correlating pathology with B-mode ultrasonographic imaging has shown that fibrous plaques have a highly echogenic quality. As the lipid content of the plaque increases, the plaque becomes more echolucent[14].

Johnson *et al.*[15] classified asymptomatic plaques according to ultrasonographic characteristics into calcified, dense and soft. At the end of a 3-year follow-up a large proportion of patients with no symptoms and soft plaques had become symptomatic, while only a small proportion of those with calcified plaques developed symptoms[15]. Hennerici *et al.*[16] reported that patients with fibrous carotid plaques who were followed for 18 months had a tendency to remain stable. In contrast, plaque progression was common in those with soft and complex calcified plaques. Spontaneous regression of minor carotid atheroma occurred in soft plaques and corresponded to a reduction in plaque volume. There was a lack of regression in fibrous and calcified plaques[16]. In a recent report from the Committee on Standards in Non-invasive Vascular Testing, it was recommended that plaque characterization should be confined to homogeneous or heterogeneous types[17]. In the present classification, plaque types 1 and 4 were both homogeneous, but homogeneously echolucent lesions were associated with symptoms while homogeneously echogenic plaques were not. The authors are not aware of previous reproducibility studies on carotid plaque characterization, and have shown that there is good inter-observer agreement.

Steffen *et al.*[2] adopted a similar ultrasonographic characterization of carotid artery atheroma and reported that in symptomatic arteries, for all degrees of stenosis, type 1 and 2 lesions were more common (67 per cent), whereas in patients without symptoms the commoner lesions were types 3 and 4 (86 per cent). The present study has confirmed their findings for patients with stenosis >70 per cent. In the light of the above, it is suggested that the present classification might be used in prospective natural history studies of subjects with no symptoms and high-grade stenosis. It might also be used in future studies in which those without symptoms are randomized to operation or medical management. In patients with symptoms and moderate (30–69 per cent) stenosis, the results of the European Carotid Surgery Trial[5] have not shown any benefit of surgery over medical treatment. Perhaps the adoption of plaque characterization would allow recognition of a high-risk subgroup that might benefit from surgery.

Announcement

Inauguration of the Subsection (Division) for Vascular Surgery within the European Union of Medical Specialists

On 6 June 1993 the inaugural meeting took place in Edinburgh, UK, of the subsection for vascular surgery of the monospecialty section for general surgery of the European Union of Medical Specialists (UEMS), an event that marks a small but significant step for the advancement of vascular surgery within the European Community (EC). Establishment of this committee is the first official recognition in Europe of vascular surgery as an entity, albeit one still within the embrace of general surgery, and its purpose is to advise Brussels on matters relating to vascular disease and its treatment within member states.

Each member country has one representative who will serve for 4 years, renewable for a further term. The Chairman and Secretary of the General Surgical Monospecialty Section are *ex officio* members. In addition, the European Society for Vascular Surgery and European Chapter of The International Society for Cardiovascular Surgery may each send a representative to attend meetings but without entitlement to vote. Similar privileges are extended to the Council of Vascular Surgeons.

The constitutional framework within which the subsection will function demands that it is accountable primarily to the management council of the UEMS through the monospecialty section of general surgery. However, it is the intention to disseminate information about its activities to all vascular surgeons in the EC through national representatives.

Matters relating to training will occupy a major part of the proceedings of the subsection. Other topics on the agenda include: preparation of advice on the level of provision of vascular services appropriate for EC countries, promotion of practice guidelines relating to vascular procedures, recommendations on priorities for allocation of research funds, advising on measures to prevent vascular disease, and monitoring vascular surgical activity and standards of practice in member states.

Underlying many of these is the issue of the future of vascular surgery within the Community, whether it is to remain a subspecialty or become a specialty independent of general surgery. The most important consequence of monospecialty status would be the option to establish an independent European Board with the authority to assess candidates and award an EC diploma or certificate of specialist training in vascular surgery. One of the tasks of the subsection will be to gauge the opinion of vascular surgeons in the EC on such issues.

The essential purpose of this new committee is to promote a high standard of clinical practice in vascular surgery throughout the EC. This is an objective with which vascular surgeons of all member countries should be able to identify and towards which it is hoped they will be prepared to lend active support.

P. L. Harris
Chairman
Subsection for Vascular Surgery of the UEMS

Mr A. R. Naylor, Department of Surgery, Leicester Royal Infirmary, PO Box 65, Leicester LE2 7LX, UK

A radioisotopic method of quantifying mean cerebral transit time was used to assess the immediate effects of carotid endarterectomy on cerebrovascular reserve (CVR) in 69 patients. In addition, serial postoperative data were acquired on CVR, clinical status and non-invasive imaging of the internal carotid arteries in 56 patients over a period of 6–48 (median 24) months. Twenty-one patients (30 per cent) had preoperative evidence of impaired CVR in the symptomatic hemisphere. Within 4 days of surgery, however, reserve had returned to normal in 17 of the 21 patients. During follow-up, four of the 56 patients developed recurrent stenosis (>50 per cent) or occlusion of the artery operated on but only two of these had impairment of CVR and none was symptomatic. Three patients suffered recurrent transient ischaemic attacks (TIAs) but none had recurrent internal carotid artery disease or impaired CVR. One patient suffered a TIA in the territory of the non-operated artery during follow-up in association with disease progression and CVR impairment. However, the TIA preceded recognition of either of these changes. Twelve other patients had (or developed) stenosis (>50 per cent) in the non-operated artery during follow-up but none was symptomatic or developed impairment of CVR. Although assessment of CVR provided useful information on the frequency of haemodynamic compromise before carotid endarterectomy and on the natural history of disease progression, neither serial assessment of reserve nor non-invasive imaging of the carotid bifurcation influenced clinical practice during follow-up.

There is considerable variability with regard to the haemodynamic effect of extracranial internal carotid artery stenosis on cerebral blood flow (CBF). Patients with a good collateral circulation maintain normal CBF without recourse to other compensatory mechanisms and have normal cerebrovascular reserve (CVR). If, however, the collateral circulation is poor, the brain is usually still able to maintain CBF by progressive dilatation of the cerebral resistance arterioles, i.e. there is a dynamic state in which CBF is maintained by a simultaneous increase in the cerebral blood volume (CBV). These patients will, however, have some degree of impairment of CVR: they have a reduced capacity to undergo further compensatory vasodilatation.

The concept of impaired CVR is of considerable current interest. Preliminary studies[1–4] suggest that patients with impaired reserve may be more likely to suffer a stroke or neurological deficit during carotid endarterectomy than those with normal CVR, possibly because the former are more susceptible to minor embolic phenomena or low-flow states. It might be speculated that early recognition of impairment of CVR could identify patients at risk of developing recurrent symptoms following carotid endarterectomy.

The aim of this study was to evaluate the immediate and long-term effects of carotid endarterectomy on CVR, and to correlate patterns of restenosis and disease progression during follow-up with the development of impairment of CVR and clinical outcome.

Patients and methods

Seventy-one consecutive patients undergoing carotid endarterectomy at Edinburgh Royal Infirmary were included in the study. Two who suffered major perioperative strokes and who did not undergo postoperative assessment were excluded from further analysis. Permission for the study was obtained from the Lothian Area Surgical Ethics Committee and the UK Administration of Radioactive Substances Advisory Committee, and patients were entered after obtaining their informed consent.

Preoperative assessment

All patients underwent carotid angiography, computed tomography (CT) and an evaluation of CVR. The degree of stenosis in the internal carotid artery was determined as the maximal biplane diameter reduction as a percentage of the normal diameter of the artery above the stenosis[5].

The principle underlying assessment of CVR is that, as the pial vessels undergo compensatory vasodilatation, there is a simultaneous increase in CBV. Accordingly, impairment of reserve can be recognized by: (1) testing the residual capacity of arterioles to undergo further dilatation in response to hypercapnia[5,6]; or (2) generating, after measurement of basal CBF and CBV, a final image that displays the ratio of CBF to CBV. Studies[7] using positron emission tomography (PET) suggest that the ratio of CBF to CBV is one of the most sensitive indicators of impairment of reserve. According to the basic flow equation (flow = volume/time), this ratio is an expression of the reciprocal of mean cerebral transit time (MCTT), i.e. any compensatory increase in CBV will cause a simultaneous increase in MCTT. This fact was acknowledged by Gibbs *et al.*[7], who recognized that quantification of MCTT could provide a simpler alternative to PET for studying CVR.

A method has been developed for quantifying regional and hemispheric MCTT following an intravenous injection of ^{99m}sodium pertechnetate[8,9]. After correction for the error due to bolus dispersion[8], the technique generates a parametric image of cerebral transit time (*Figure 1*) in which each colour represents an increment of 0·5 s in time (range 0–15 s). Although regional variations in transit time can be determined from the colour scale, the computer determines the mean transit time for each hemisphere and also the interhemispheric difference

0007-1323/93/101278-05 © 1993 Butterworth-Heinemann Ltd

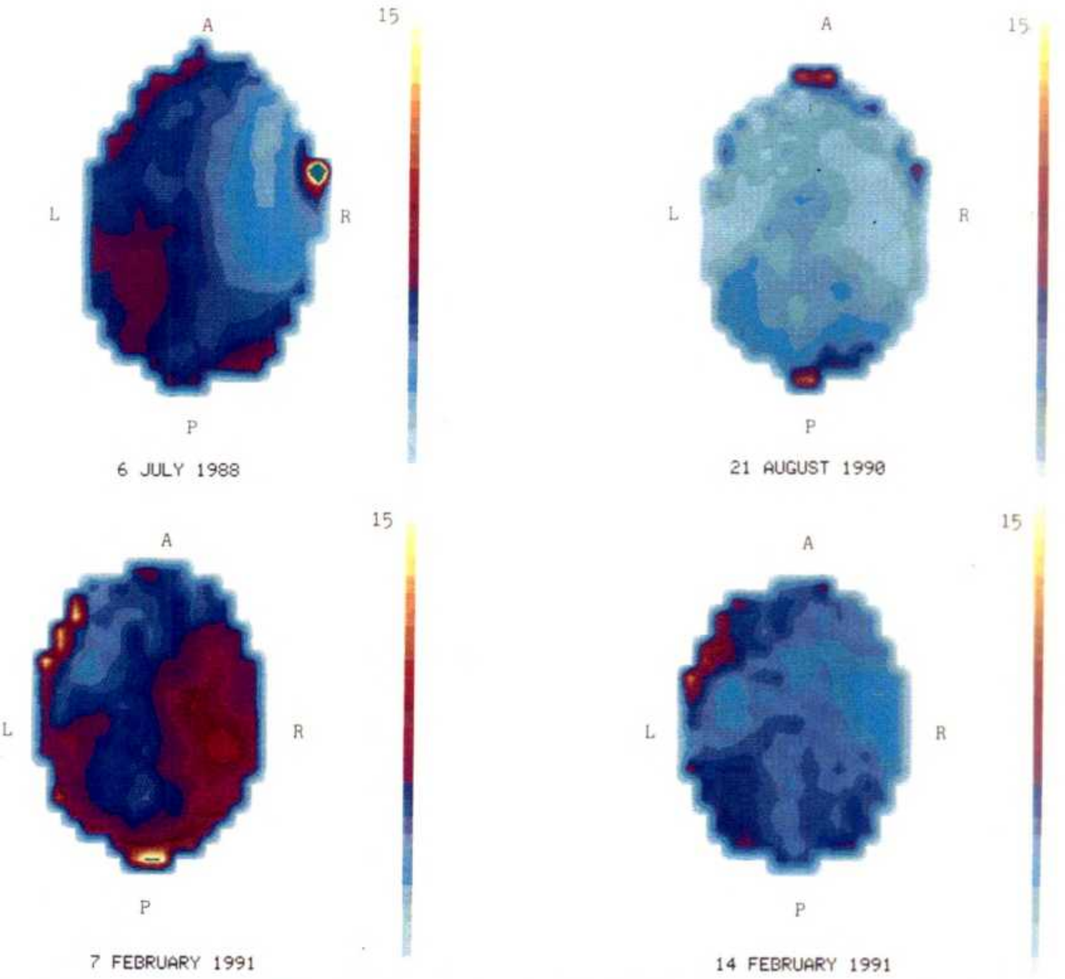

Figure 1 *Serial mean cerebral transit time (MCTT) studies in one patient over 29 months following carotid endarterectomy.* **a** *Initial preoperative study in a patient with 90 per cent stenosis of the left internal carotid artery. A, anterior; P, posterior; L, left hemisphere; R, right hemisphere, i.e. one is looking down on the skull vertex. Each colour represents an increment of 0·5 s in MCTT (range 0–15 s)*

in MCTT. *Figure 1b* shows a normal study. The normal pattern is one of shorter MCTTs at the front of the brain with longer transit times posteriorly but, most importantly, close symmetry in transit time is maintained between hemispheres.

In comparative studies with transcranial Doppler ultrasonography (no PET scanner is available to the authors), it has been shown[9] that hypercapnia causes a significant and symmetrical reduction in hemispheric MCTT, and a symmetrical and bilateral increase in blood flow velocity in the middle cerebral artery. In addition, blood flow velocity changes in direct proportion to the reciprocal of hemispheric MCTT, i.e. the CVR[9].

The normal range of mean hemispheric transit time (2·2–7·7 s) reflects the wide range of interindividual variability that is typical of all methods used to measure the parameters of cerebral circulation. Interhemispheric MCTT symmetry is, however, closely maintained throughout the physiological range of end-tidal carbon dioxide levels (upper 95 per cent confidence limit for interhemispheric MCTT difference[8,9] 0·6 s). In the present study, specific use was made only of those values of hemispheric MCTT and interhemispheric asymmetry that had been determined by the system computer, i.e. impaired CVR was not diagnosed on the basis of visual interpretation of the image. Accordingly, impaired reserve was defined as a hemispheric MCTT $>7{\cdot}7$ s or significant interhemispheric transit time asymmetry $\geqslant 0{\cdot}7$ s.

Figure 1a shows a typical example of impaired CVR in a patient with 90 per cent stenosis of the left internal carotid artery (no significant disease in the contralateral artery). Note the loss of normal interhemispheric MCTT symmetry with prolongation of transit times throughout the territory of the left artery.

Operative technique

Carotid endarterectomy was performed under normotensive normocarbic general anaesthesia with systemic heparinization. The nerve to the carotid sinus was not anaesthetized or divided in any patient and all but one arteriotomy was closed with a vein patch. Patients had carotid shunts inserted using the criterion of slowing of the cerebral function monitor or an internal carotid artery stump pressure <50 mmHg. Five patients recovered from anaesthesia with a transient minor intraoperative neurological deficit, three of which represented slight worsening of a pre-existing deficit. The deficit resolved within days in all but two patients, who still had some residual weakness of the hand at 7 days. All patients received aspirin after operation, unless contraindicated.

Postoperative assessment

MCTT studies were repeated on day 4. All patients suffering an intraoperative neurological deficit underwent re-exploration, intravenous digital subtraction angiography (DSA) or duplex ultrasonography of the operated internal carotid artery. Fifty-six patients were then serially evaluated over 6–48 (median 24) months, with repeated assessment of clinical status and CVR, and non-invasive imaging of the carotid bifurcation (initially by intravenous DSA, latterly by duplex ultrasonography and Doppler waveform analysis) every 6 months for the first year and annually thereafter. Endpoints of the study were the development of cerebrovascular symptoms, impaired CVR, or the presence of internal carotid artery stenosis >50 per cent or occlusion. In two patients, serial imaging of the CVR was abandoned after 24 months because of poor cardiac output. Thirteen patients did not undergo serial postoperative assessment. Twelve had not reached their first 6-month follow-up by completion of the study, and one was found to have metastatic prostatic carcinoma within months of operation and was unfit for review.

Results

Forty-six patients presented with transient ischaemic attack (TIA) or amaurosis fugax, 20 with stroke (16 with residual deficit), and three with central retinal artery occlusion; 56 had a symptomatic stenosis >50 per cent. Fifty-eight patients had either no disease or stenosis $\leqslant 50$ per cent in the non-operated artery, seven a contralateral artery stenosis >50 per cent and four a contralateral carotid occlusion. Nineteen patients had a hypodense area in the symptomatic hemisphere on CT, consistent with an area of old infarction, while nine had infarction in the non-operated hemisphere.

Immediate effect of carotid endarterectomy on cerebrovascular reserve

Twenty-one patients (30 per cent) had preoperative evidence of impaired CVR in the symptomatic hemisphere and all had internal carotid artery stenosis >60 per cent. None of the seven patients with a contralateral artery stenosis >50 per cent had evidence of impaired vascular reserve, but three of the four with a contralateral occlusion had an impaired reserve in the non-operated hemisphere. One of the latter had bilateral impairment of CVR.

Of the 21 patients with impaired reserve in the symptomatic hemisphere, the CVR returned to normal in 17 within 4 days of operation. In only one of the remaining four patients had the CVR not returned to normal by 6 months. Four patients had a normal preoperative CVR study but then developed significant abnormality after operation. In two patients MCTTs in the symptomatic hemisphere were very short and probably represented transient postoperative hyperaemia. Two, however, developed impaired CVR in the symptomatic hemisphere. Because of the unexpected nature of these findings intravenous DSA was undertaken, which showed in both that the operated internal carotid artery had occluded without symptoms.

Long-term effect of carotid endarterectomy on cerebrovascular reserve

The hemisphere operated on (Table 1). Fifty-one of the 56 patients had no evidence of either recurrent disease in the operated internal carotid artery or impaired CVR during follow-up. Three patients suffered TIAs at 14, 15 and 23 months respectively; none had an obvious cardioembolic source but one had stenosis of the ipsilateral external carotid artery.

Two patients had impaired reserve in the operated hemisphere at 6 months and both had suffered asymptomatic occlusion of the operated artery (verified angiographically). The first was discussed earlier, having been noted to have unexpected impairment of vascular reserve after operation. The second initially presented with impaired CVR and then suffered an intraoperative neurological deficit. Re-exploration found no abnormality of the segment operated on. The first postoperative MCTT study, however, remained abnormal and it may be that by this time the internal carotid artery had occluded asymptomatically. Interestingly, serial CVR studies in these two patients showed progressive improvement, and by 12 months both had returned to normal and remained so when rechecked at 24 months.

Table 1 *Long-term outcome for the operated artery in 56 patients*

	Impaired CVR	Normal CVR
Recurrent disease (>50% stenosis or occlusion)	2*	2†
No recurrent disease	1	51‡

CVR, cerebrovascular reserve. *Occlusion of both internal carotid arteries; impaired CVR had returned to normal 12 months after surgery; †60 per cent stenosis at 24 months, 75 per cent at 36 months; ‡three patients had recurrent transient ischaemic attacks

Two patients developed significant restenosis in the operated internal carotid artery during follow-up; neither stenosis was symptomatic or associated with impaired CVR. The remaining patient had no evidence of recurrent carotid disease but had persistently impaired vascular reserve in the operated hemisphere (up until last review at 3 years). This patient had had preoperative evidence of impaired reserve as well as a residual neurological deficit (which worsened transiently during operation); perhaps more importantly, he had preoperative CT evidence of three cortical infarcts in the territory of the symptomatic middle cerebral artery. This may explain why the abnormality in CVR did not resolve after operation.

The non-operated hemisphere (Table 2). Forty of the 56 patients remained asymptomatic throughout follow-up with no evidence of either disease progression or impairment of CVR. Twelve patients had internal carotid artery stenosis >50 per cent but normal vascular reserve; in five this represented no change from the preoperative findings while in seven there was evidence of significant disease progression. None of the twelve developed any clinical symptoms, apart from one hypertensive patient who suffered a fatal haemorrhage in the non-operated hemisphere at 24 months.

The most interesting subgroup were the four patients with significant contralateral carotid disease and evidence of impaired CVR. Three were known before operation to have occlusion of the internal carotid artery. Although surgery did not appear to alter the overall degree of interhemispheric MCTT asymmetry, regional transit times were generally reduced throughout both hemispheres, suggesting at least partial improvement in CVR. The serial MCTT studies in the fourth patient in this group are shown in *Figure 1*. She presented with 90 per cent stenosis of the left internal carotid artery and only minor irregularity of the right artery on ultrasonography and angiography (*Figure 2a*). Her preoperative transit time study (*Figure 1a*) showed evidence of impaired CVR in the symptomatic left hemisphere (interhemispheric MCTT difference 2·0 s). After operation the transit study results returned to normal, with restoration of symmetry (interhemispheric MCTT difference 0·3 s). Ultrasonography (duplex plus Doppler ultrasonographic waveform analysis) at 6 and 12 months showed no significant stenosis at either bifurcation, and transit time study results remained normal. At 2 years after operation, while the patient was still asymptomatic, ultrasonography suggested that stenosis in the non-operated artery had progressed to about 50 per cent but there was still no corresponding abnormality in vascular reserve (*Figure 1b*). However, 6 months later she presented with a TIA. By this

Table 2 *Long-term outcome for the non-operated artery in 56 patients*

	Impaired CVR	Normal CVR
Stenosis >50% or occlusion		
Disease static	0	5

CVR, cerebrovascular reserve. *Stenosis increased from 10 to 90 per cent over 30 months; patient suffered a transient ischaemic attack at 29 months. †Stenosis increased in two patients from 50 to 75 per cent and from 50 to 80 per cent over 12 months, in three from 40 to 60 per cent, from 75 to 90 per cent and from 30 to 80 per cent over 24 months, and in two from 30 to 60 per cent and from 0 to 70 per cent over 36 months

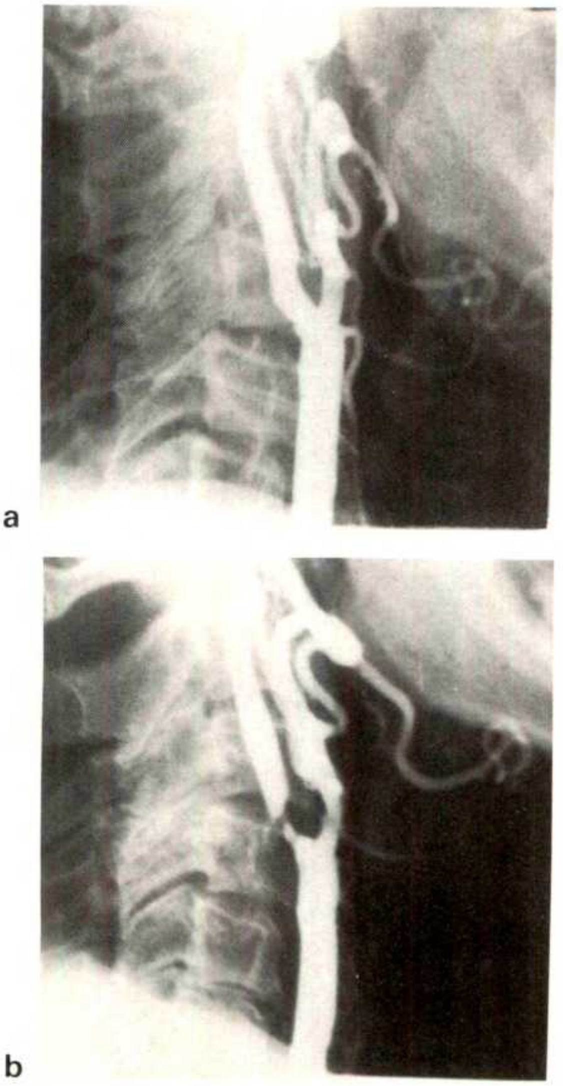

Figure 2 *Angiography of disease progression in the non-operated carotid bifurcation of the patient described in* Figure 1. **a** *Minimal irregularity at the time of first carotid endarterectomy;* **b** *severe stenosis 29 months after the original carotid surgery when the patient presented with a transient ischaemic attack*

time ultrasonography, and subsequently angiography, revealed a very tight stenosis (*Figure 2b*). When the transit time study was repeated (*Figure 1c*) there was clear evidence of impaired vascular reserve throughout the right hemisphere (inter-hemispheric MCTT difference 1·7 s). At operation, the plaque was found to have ruptured, with overlying thrombus and loose atheromatous debris. After operation CVR study results again returned to normal (*Figure 1d*).

Discussion

Evaluation of the haemodynamic state of the cerebral circulation must take into account the dynamic changes that occur in the ratio of CBF to CBV. This awareness has led to the development of a number of methods designed to assess the capacity of the cerebral circulation to undergo further vasodilatation. None, however, specifically tests the individual contributions of the carotid and vertebrobasilar inflows but rather the capacity to respond of the cerebral circulation as a whole. The most common of these methods is the response to hypercapnia or following administration of acetazolamide, although carbon dioxide reactivity is a partially independent mechanism to autoregulatory vasodilatation in response to a declining cerebral perfusion pressure[10]. Using a hypercapnic stimulus, CVR has been evaluated using conventional ^{133}xenon washout methods[5], single photon emission computed tomography[11], transcranial Doppler ultrasonography[6] and PET[7,12]. Stress tests, however, require two separate studies, patient compliance and (in the case of the tomographic methods) minimal head movement during data acquisition. Moreover, tomographic equipment is not widely available to clinicians in the UK and doubt has been cast[13] on the validity of some of the agents used to measure carbon dioxide reactivity.

The transit time method is one of several means of studying CVR with the virtues of speed, simplicity, availability and low cost. However, it is limited by the lack of anatomical precision offered by tomographic methods; it cannot individually quantify either CBF or CBV; and it requires a good cardiac output. Poor cardiac output is the principal reason for poor diagnostic imaging. Its application is based on a sound theoretical basis derived from PET studies[7] and it has been proposed[14] that changes in MCTT should parallel changes in perfusion pressure. While unable to demonstrate a relationship between the oxygen extraction fraction and either CBF or CBV, Gibbs and colleagues[7] found a clear relationship between oxygen extraction fraction and the ratio of CBF to CBV. As the stenosis becomes more significant haemodynamically, CBV increases to maintain CBF. The corresponding increase in MCTT probably occurs at capillary and precapillary levels, and permits an increase in the oxygen extraction fraction by virtue of the increased surface area and time available for diffusion[15]. Moreover, it has been shown that once the ratio of CBF to CBV is $<5{\cdot}5$ (equivalent to a hemispheric MCTT[8] >11 s), there is always an increase in the oxygen extraction fraction. This implies that the lower limits of autoregulation and perfusion reserve have been reached[7,16]. Such an extreme situation was encountered in only one of the present patients with bilateral impaired CVR (symptomatic hemisphere MCTT 9·4 s, asymptomatic hemisphere MCTT 11·8 s) and bilateral carotid disease (90 per cent stenosis and contralateral occlusion respectively).

In the present study, carotid endarterectomy restored normal CVR in 81 per cent of patients with preoperative abnormalities; this is in line with the experience of others[17–19]. However, the effect of carotid surgery on CBF and CVR is influenced by patient selection. The main haemodynamic effect of carotid endarterectomy is an increased flow in the internal carotid artery and a redistribution of cerebral perfusion as the need for collateral flow is reduced[20]. In a comprehensive review, Schroeder and Jones[3] found that patients with carotid stenosis <50 per cent had no significant increase in CBF after operation, while those with stenosis >50 per cent had a variable response but tended to show an increase in CBF. The most marked increases in postoperative CBF were in patients with stenosis >80 per cent, i.e. those most likely to have impaired CVR.

The present study has also shown that the restoration of normal CVR is generally maintained throughout follow-up and correlates well with non-invasive imaging of the carotid bifurcation. Little emphasis should be placed on transient early asymmetries that might be due to postoperative hyperaemia, as these have almost invariably disappeared[5] by 6 months. However, the unexpected finding of residual (or new) impairment of CVR in the symptomatic hemisphere should raise the possibility of an asymptomatic carotid occlusion. Moreover, the present study has demonstrated that, with time, any impairment in CVR associated with carotid occlusion might return to normal as the collateral circulation develops.

Although the authors' policy of assessment of CVR and non-invasive imaging of the endarterectomy site has provided useful information on the durability of carotid endarterectomy and the rather unpredictable nature and sequeliae of disease progression, it has not led to any changes in clinical practice. The hypothesis that recurrent symptoms might be anticipated by preceding changes in CVR has not been borne out; none of the patients with recurrent symptoms in the territory of the operated internal carotid artery had either significant recurrent disease or CVR abnormality. Similarly, while 13 patients under follow-up had significant stenosis in the non-operated artery (five static, eight as a consequence of disease progression), only one developed symptoms. Although the TIA in this patient was associated with the development of impaired CVR, she had already presented clinically before evidence was forthcoming of the rapid disease progression and haemodynamic impairment. Because of the findings at operation, it is presumed that this patient's symptoms and disease progression were attributable to plaque rupture; there was nothing in the preceding 2 years of follow-up to differentiate her from the other seven patients with disease progression. In agreement with other authors, therefore, no compelling clinical or cost-effective indication has been found for continuing with serial assessment of either CVR or the carotid bifurcation beyond the early postoperative period. Such investigations should be reserved for the very few patients who develop secondary symptoms.

Cryostripping the long and short saphenous veins

T. R. Cheatle, B. Kayombo and M. Perrin

Unite de Pathologie Vasculaire Jean Kunlin, Clinique du Grand-Large, Decines Charpieu, France

Correspondence to: Mr T. R. Cheatle, Flat 5,
45 New Compton Street, London WC2H 8DF, UK

Conventional stripping of the long or short saphenous vein requires two incisions. The purpose of the distal incision is to tie the vein to the stripper so that the two may be withdrawn together. Cryocoagulation avoids this requirement.

Surgical technique

After flush saphenofemoral disconnection in the groin, the trunk of the long saphenous vein (LSV) is emptied by limb elevation and catheterized with a probe connected to a liquid nitrogen cryosurgery unit (Erbe, Tubingen, Germany). When the probe has reached the upper calf, its tip is chilled to −80°C; cryocoagulation occurs within about 5 s. With the tip kept frozen, the probe is then steadily withdrawn while an assistant compresses the LSV below the site of coagulation. This causes disruption of the vein, which is then stripped upwards to the groin (*Figures 1* and *2*). Tributaries are avulsed *en route*. Since there is no distal incision, it is necessary to measure the length of retrieved vein to ensure that stripping is complete. It is important not to keep the frozen tip of the probe at one position in the leg for more than about 10 s, as this risks damage to extraluminal structures, especially the saphenous nerve. Our impression is that the technique entails less blood loss than conventional stripping, although this has not been quantified.

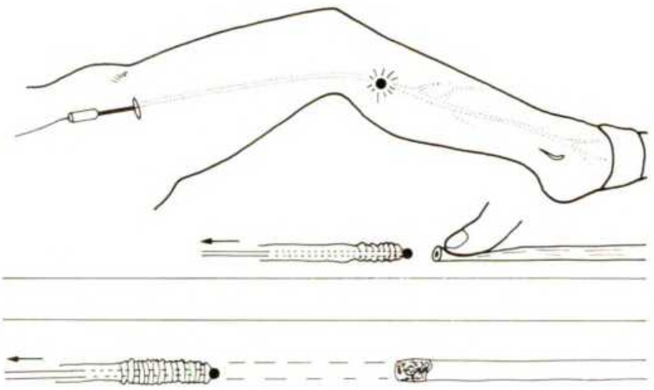

Figure 1 *Diagrammatic representation of cryostripping*

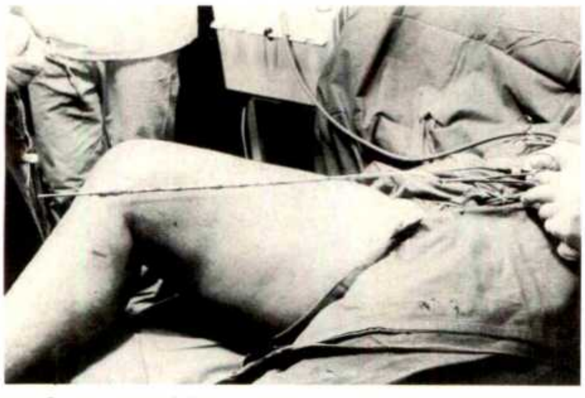

Figure 2 *A stripped long saphenous vein after withdrawal of the cryoprobe. A pen mark below the patient's knee indicates the point at which stripping was started*

Discussion

Between 1 January and 30 June 1992 one surgeon (M.P.) stripped 386 LSVs and 75 short saphenous veins (SSVs). Cryostripping was used in 105 (27 per cent) and 16 (21 per cent) cases respectively. The authors' indications for cryostripping are:

1. When multiple distal avulsions of varicosities are not being performed, and where the cosmetic benefit of avoiding a distal incision is therefore maximized. The majority of such patients had had sclerotherapy to control varicosities.
2. When one or more large tributaries of the LSV in the groin, such as the anteromedial or posterolateral superficial veins of the thigh, needs to be stripped in addition to the LSV itself. These veins can all be stripped upwards through a single groin dissection.
3. When liposclerotic skin in the calf makes a distal incision hazardous. This especially applies to the SSV.

In an attempt to identify complications, 100 patients who had undergone cryostripping were sent a postal questionnaire in which they were asked about adverse postoperative events. Sixty-one responded, of whom 11 (18 per cent) said they had suffered complications. These comprised two patients with superficial thrombophlebitis, seven in whom a numb patch of skin occurred, one with oedema and one with nervous depression. The nine instances of thrombophlebitis or hypoaesthesia were all transient and have resolved completely. The authors are aware of one case early in their experience where the saphenous nerve was permanently damaged, probably by prolonged freezing at the site of vein disruption.

Since the concept of cryostripping was first introduced by Milleret[1], the technique has become an established part of the authors' armamentarium. It is simple, inexpensive and slightly quicker than conventional stripping since no distal incision, dissection or closure is required. It is recommended to all surgeons performing regular saphenous stripping.

Suture length to wound length ratio and healing of midline laparotomy incisions

The effect of suture length to wound length ratio on the healing of midline laparotomy wounds closed with a continuous suture was evaluated in a prospective clinical trial. All patients undergoing abdominal procedures through a midline incision were included except those with an incisional hernia after previous midline operation. The total incidence of wound infection was 36 of 454 patients (7·9 per cent) and wound dehiscence requiring reoperation occurred in three patients (0·7 per cent). Incisional hernia was found in 18·7 per cent of 363 patients alive 12 months after surgery. Multivariate analysis identified the suture length to wound length ratio, age and major wound infection as independent risk factors for the development of hernia, which occurred in 9·0 per cent of patients when the suture length to wound length ratio was ≥4 and in 23·7 per cent ($P = 0{\cdot}001$) when it was <4. The suture length to wound length ratio is an important parameter for healing of midline incisions closed with a continuous suture technique. The incidence of incisional hernia is lower when such wounds are sutured with a ratio ≥4.

Closure of midline laparotomy incisions with a single layer of continuous monofilament suture is a well established method[1-8]. Trials have compared interrupted and continuous suture techniques and found the latter to be more rapid, whereas the safety of the two methods appears to be similar[9-12].

Experimental evidence suggests that continuous suturing gives the best results when the suture length to wound length ratio is 4:1, i.e. the length of suture material consumed is four times the length of the wound[1,6,13-15]. An optimal suture length to wound length ratio has yet to be determined in a clinical trial. This prospective study assessed how this ratio affects early and late healing of midline laparotomy wounds.

Patients and methods

A prospective trial was started in August 1989 in which all surgeons, including residents in training, participated. All patients undergoing abdominal surgery through a midline incision were eligible for the trial; only those with an incisional hernia after previous midline surgery were excluded. Patients were stratified according to age, sex, previous midline laparotomy, urgency of operation and degree of operative contamination[16,17].

The fascia was sutured with a continuous single-layer mass-closure technique including all layers except skin. The surgeon was free to choose whether peritoneum was included in the suture or not. The starting knot was a modification of the half blood-knot, and the suture was ended with a chain stitch knot[18-21]. For reasons not relevant to the present study, patients were randomized to closure with polydioxanone or nylon, no. 1, delivered in lengths of 150 cm (*Figure 1; Table 1*). The length of the incision was measured after closure of the fascia and the length of suture consumed (150 cm − length of suture remnants) measured for calculation of the suture length to wound length ratio.

Early wound complications were recorded. Infection was defined as purulent discharge from the wound; bacteriological cultures were not mandatory. Wound infection was classified as minor or major. Major wound infection was accompanied by general symptoms and an increased length of hospital stay[16,22].

Patients alive 12 months after surgery were examined for the presence of incisional hernia. This was defined as a palpable defect in the fascia, or a protrusion beyond the level of the fascia with the patient examined supine lifting both legs and coughing or straining in an erect position. Examinations were carried out by the same surgeon (L.A.I.) except when patients had moved from the area, when they were examined by a local physician.

Univariate statistical analysis used the χ^2 test with Yates' correction or Fisher's exact test as appropriate. Factors identified as significant on univariate analysis were subjected to multivariate analysis using multiple linear regression. Differences were regarded as significant at $P < 0{\cdot}05$.

Results

From August 1989 to March 1991, 454 patients were entered into the trial. The length of the laparotomy incision ranged from 10 to 86 (mean 27) cm. The mean suture length to wound length ratio was 3·6.

Early results

Minor and major wound infection each occurred in 4·0 per cent of patients. The suture length to wound length ratio did not affect the incidence of infection. Wound dehiscence requiring resuture occurred in three patients (0·7 per cent). In one of these, suture and wound lengths were not registered, but closure in the other two patients was with a suture length to wound length ratio of 1·25.

Late results

Eighty-six patients died within 12 months of surgery, three were excluded from late follow-up because of early wound dehiscence and two were ineligible because of violation of the study protocol. The remaining 363 patients were all available for follow-up examination. The overall incidence of incisional hernia 12 months after surgery was 18·7 per cent. The incidence of hernia was related to the suture length to wound length ratio. When the ratio was <4, hernia occurred in 23·7 per cent of patients (57 of 241), whereas the incidence was 9·0 per cent (11 of 122) if the ratio was ≥4 ($P = 0{\cdot}001$; *Table 2*). The two groups of patients were comparable with regard to all variables recorded (*Table 1*). The association between suture length to wound length ratio and hernia was similar for both suture materials used (*Figure 1*).

0007-1323/93/101284-03 © 1993 Butterworth-Heinemann Ltd

On univariate analysis, sex, previous midline laparotomy, emergency operation and minor wound infection were not related to the subsequent development of hernia whereas age, length of incision and major wound infection were significantly correlated. Hernia was found in 62 of 279 patients (22·2 per cent) older than 45 years compared with six of 84 (7 per cent) aged 45 years or younger ($P < 0{\cdot}01$; *Figure 2*). The hernia rate was 25·2 per cent (33 of 131) when incisions were longer than 27 cm and 15·1 per cent (35 of 232) for those of 27 cm or shorter ($P = 0{\cdot}03$). The incidence of hernia was six of 14 patients with major wound infection compared with 58 of 332 when there was no infection ($P = 0{\cdot}04$). The suture length to wound length ratio affected the hernia rate even in the presence of major wound infection; hernia occurred in six of eight of these patients when the ratio was <4 but in none of six when it was ≥4 ($P < 0{\cdot}01$).

Stepwise forward multiple linear regression analysis was performed, testing the suture length to wound length ratio, age, major wound infection and length of incision as predictors of hernia. Multivariate analysis identified the suture length to wound length ratio, age and major wound infection as independent risk factors, whereas wound length was not found to affect the incidence of hernia significantly.

Discussion

It has previously been proposed that the suture length to wound length ratio is associated with the incidence of complications of continuously sutured incisions[1,6,13–15]. The present results support this hypothesis, as a strong correlation between the ratio and subsequent incisional hernia was demonstrated (*Table 2*). A ratio <4 resulted in a 2·5-fold higher incidence of hernia than was found for wounds sutured with a ratio ≥4.

Concerning early complications, the incidence of wound infection did not correlate with the suture length to wound length ratio and patients with wound dehiscence were too few to permit analysis. The low incidence of dehiscence indicates that suture quality and basic surgical technique, such as suture handling and knotting, were adequate. Two instances of wound dehiscence occurred in patients with an extremely low suture length to wound length ratio; this should be regarded as a failure in suture technique.

The overall incidence of incisional hernia in the present study may seem high, but others have applied similar criteria of fascia healing 12 months after surgery and reported comparable rates[23–25]. Furthermore, with the liberal inclusion criteria used in the present trial, several factors considered to increase the risk of postoperative hernia were present in a substantial proportion of patients, including old age, incision through scar tissue, emergency operation, length of incision exceeding 18 cm, and major wound infection[4,26,27]. Of these, the present study identified a suture length to wound length ratio <4, age above 45 years and major wound infection as significant and independent risk factors. To date, 14 of the 68 patients (21 per cent) who developed hernia have needed operative repair. This shows that, although the definition of hernia was rather broad, a significant number of patients have already presented with symptoms severe enough to require surgical intervention.

An association between wound sepsis and incisional hernia has been reported by others[4]. It is an interesting finding in the present study that proper surgical technique may reduce the incidence of hernia even in this high-risk group of patients.

The suture length to wound length ratio depends on the size of tissue bites, the distance between bites and the tension on the suture. The relative importance of these factors for subsequent wound healing is uncertain, as clinical studies on this issue are few[16]. As the trial continues, it might be possible to assess the separate effect of these technical factors on clinical outcome.

An intervention was made in the trial when preliminary results became available in April 1991. Participating surgeons were then urged to adjust their suture technique towards a suture length to wound length ratio of 4:1. The compliance of the surgeons with these recommendations as well as possible benefits of altered technique will become evident as the study continues.

In a prospective study of 879 triple-lumen catheters, 219 pulmonary artery catheters, 31 double-lumen and six single-lumen catheters used for the administration of total parenteral nutrition over a 1-year period, the overall complication rate was 12·5 per cent (14·7 complications per 1000 catheter-days) and the catheter-related sepsis rate 4·4 per cent (5·2 per 1000 catheter-days). The probability of development of catheter-related sepsis did not increase with the duration of catheterization. There were no differences in the rate of complications associated with 427 catheters changed by replacement at a new site compared with 159 lines changed over a guidewire. These data support the use of multilumen central venous catheters for the administration of total parenteral nutrition. They suggest that a routine weekly change of line is unnecessary; catheters should be changed only on the development of a complication. When it is required, a catheter should be changed by replacement over a guidewire.

The high concentration of dextrose, lipids and other nutrients in total parenteral nutrition (TPN) solutions increases the risk of septicaemia when central venous catheters are used for their delivery[1–3]. TPN is normally therefore delivered through a dedicated single-lumen central venous line[4]. Strict protocols regarding the use of such catheters are recommended by nutritional support teams[5,6].

Requirements for providing central venous access for the administration of fluids and medications, and for monitoring of central venous and left atrial pressure in critically ill patients, bring into question the necessity for a central venous line dedicated solely to the administration of TPN[1]. This study audited the complications associated with multiuse and multiuser central venous catheters employed for the administration of TPN solutions and the practice of routinely changing such catheters to minimize infective complications.

Patients and methods

Data including the type, site and method of placement were collected for all central venous catheters used for the administration of TPN between 1 November 1988 and 1 November 1989. On removal of the line, the duration of catheterization, the nature of any complication, the reason for removal and the results of culture of the catheter tip, and of peripheral and central venous blood cultures were recorded.

TPN was administered through 1135 percutaneously placed catheters, which comprised 879 triple-lumen devices, 31 double-lumen lines, six single-lumen catheters (Arrow-Howes 7 Fr; Arrow International Equipment, Reading, Pennsylvania, USA) and the side port of 219 pulmonary artery catheters (Swan–Ganz VIP catheter, 7·5 Fr; American Edwards, Anasco, Puerto Rico).

Central venous catheters were inserted at the bedside by physicians on the nutritional support team, by the staff of the intensive care units or by other physicians under the supervision of a member of the nutritional support team. The subclavian vein was cannulated in 528 instances and the internal jugular vein in 579. The external jugular vein was used for 24 central venous catheters, and four catheters were placed in the femoral vein.

The policy of the nutritional support unit was to change central venous catheters at the beginning of TPN therapy and thereafter only if complications developed. Patients managed on the intensive care unit underwent a routine change of line every 6 days, or more frequently if a change to a pulmonary artery catheter was required.

Only newly placed or changed catheters were used for the administration of TPN. One port of the central venous line was reserved for the administration of such nutrition. The administration of TPN was stopped until the line was changed if there was any possibility of contamination of the catheter by administration of unauthorized drugs. No restrictions were placed on the use of the other ports of multilumen central venous or pulmonary artery catheters, except that full aseptic technique was used for all catheter manipulations.

A site infection was defined as the presence of erythema around, or pus exuding from, a central venous line puncture site. Catheter-related sepsis was present when a culture of peripheral or central venous blood yielded the same organism as culture of the tip of the central venous line, as assessed by semiquantitative methods[7]. As catheter-related sepsis was a retrospective diagnosis, suspected sepsis was managed by one of two protocols. Patients with probable catheter-related sepsis, as defined by the development of a high fever with or without rigors in the absence of overt sepsis elsewhere, were managed by withdrawal of TPN, removal of the line, culture of the tip and simultaneous peripheral and central blood culture before the start of empirical antibiotic therapy. A new central venous line was placed, and TPN commenced 48 h after resolution of signs of sepsis. Patients with possible catheter-related sepsis, as defined by the exacerbation of a pre-existing fever and the development or worsening of cardiovascular instability, were managed by catheter change using the Seldinger technique or by replacement at a new site. If culture of the catheter tip and venous blood confirmed the presence of catheter-related sepsis, lines changed over a guidewire were removed. TPN was begun again after 48 h through a central venous line placed at a different site.

Statistical analysis

The duration of survival of catheters was analysed by Kaplan–Meier life-table analysis[8]. For the analysis of failure caused by catheter-related sepsis, lines were counted as failed on the day that they were removed for subsequently proved catheter-related sepsis; all other catheters were censored on the day of removal. For the analysis of failure from all complications, catheters were counted as failed if they had been removed for any complication and censored if they had been removed at the end of treatment or for a routine change. Log rank analysis[9] was used to determine statistical significance between life-table curves; significance was assumed for two-tailed $P < 0.05$.

Results

TPN was administered to 563 patients through 1135 central venous catheters for a total of 9641 patient-days. The median period for which patients required TPN was 13 (range 2–156) days. The median time that catheters were left *in situ* was 7 (range <1–99) days (*Figure 1*). TPN was administered through a single line in 326 patients; the range of the number of catheters in the remaining 237 patients is shown in *Figure 2*.

The mortality rate for patients receiving TPN was 22·2 per cent; no death was attributable to TPN administration. The complication rate was 12·5 per cent (14·7 complications per 1000 catheter-days). Of the 1135 central venous catheters placed, 145 complications were recorded for 142 lines. Complications of insertion, i.e. pneumothorax, air embolism and malposition, occurred in 16 catheters (1·4 per cent). Late non-infective complications, principally dislodgement and blockage, occurred in 75 catheters (6·6 per cent). Infective complications were present in 54 lines (4·8 per cent). Catheter-related sepsis was present in 50 central venous lines (4·4 per cent; 5·2 per 1000 catheter-days) (*Table 1*). The tips of 17 catheters (1·5 per cent) grew the same organisms as those cultured from distant septic foci. The organisms isolated are shown in *Table 2*.

Complications occurred at a median of 7 (range <1–99) days. Life-table analysis for survival of catheters is shown in *Figure 3*. The probability of catheter-related sepsis developing was 0·4 per cent per day in the first week that a line was used, between 0·8 and 0·9 per cent per day between weeks 2 and 4, and zero in the fifth week.

Complication	Guidewire (*n* = 159)	New site (*n* = 427)	Total (*n* = 586)
Catheter-related sepsis	5 (3·1)	22 (5·2)	27 (4·6)
Site infection	0 (0)	2 (0·5)	2 (0·3)
Pneumothorax	0 (0)	1 (0·2)	1 (0·2)
Air embolism	0 (0)	1 (0·2)	1 (0·2)
Malpositioning	4 (2·5)	2 (0·5)	6 (1·0)
Thrombosis	2 (1·3)	1 (0·2)	3 (0·5)
Blocked line	2 (1·3)	9 (2·1)	11 (1·9)
Leakage	1 (0·6)	1 (0·2)	2 (0·3)
Dislodgement	10 (6·3)	9 (2·1)	19 (3·2)
Total	24 (15·1)	48 (11·2)	72 (12·3)

Values in parentheses are percentages. The difference in complication rate between guidewire and new site change was not significant

Guidewire change of central venous line was performed on 159 occasions, either at the beginning of TPN or when treating any complication except catheter-related sepsis or site infection. Central venous catheters were changed through a new percutaneous site on 427 occasions; the indications for change are given in *Table 3*. There were no differences in the complication rate for central venous catheters changed over a guidewire compared with rates for those inserted through a new percutaneous site (*Table 4*). There was no difference in the rates of failure from catheter-related sepsis or any complication of catheters changed by guidewire compared with those of lines placed by a new puncture.

Discussion

The data presented show that the use of multilumen central venous catheters for the administration of TPN solutions in addition to intravenous fluids and drugs is safe. The data compare favourably with those of others, who have reported catheter-related sepsis rates of 2·8 per cent[10], 3·8 per cent[11], 5·7 per cent[12], 6·8 per cent[13] and 7 per cent[14] for single-lumen central venous catheters used for TPN under the supervision of a nutritional support team. The complication rates are higher for triple-lumen than for single-lumen devices. In a prospective study of 2431 lines, the catheter-related sepsis rate was 6·9 per cent for triple-lumen compared with 0·4 per cent for single-lumen central venous catheters[3]. A retrospective study of 496 central venous lines reported a catheter-related sepsis rate of 4·9 per cent for triple-lumen compared with 1·6 per cent for single-lumen devices[2]. A catheter-related sepsis rate of only 1·3 per cent was found for triple-lumen central venous catheters used for TPN compared with 0 per cent for single-lumen lines[15]. One study, however, supported the use of triple-lumen catheters, reporting a 7·9 per cent catheter-related sepsis rate for single-lumen compared with 3·8 per cent for triple-lumen devices[1].

Triple-lumen lines may be more prone to the development of catheter-related sepsis because they are manipulated more often than single-lumen devices. A sixfold increase in the catheter-related sepsis rate was reported for single-lumen catheters that had been ‘violated’ by the administration of drugs[14]. One study, however, reported no increase in the catheter-related sepsis rate for lines used variably for monitoring, antibiotic administration and withdrawal of blood[2]. In the prevention of sepsis, the care with which the catheter is handled is more important than the number of times it is manipulated.

Prophylactic changing of central venous lines to reduce the incidence of catheter-related sepsis is widely practised. Such sepsis is rare within 4 days of catheter placement[3] and this justified the practice of routine change of central venous catheters every 3–5 days[16–18]. The present data confirm that the probability of catheter-related sepsis does not increase with the duration of catheterization[19]. For a patient requiring TPN for 18 days, the sum of the probability of catheter-related sepsis for each of three lines changed at 6-day intervals is no different from the probability of sepsis in a single catheter left *in situ* for the whole period. These data are supported by a recent prospective randomized study of central lines which showed no difference in the rates of catheter-related sepsis in patients in whom catheters were changed every 3 days compared with those in whom lines were replaced as clinically indicated[20]. The practice of changing catheters places the patient at an increased risk of complications because of the greater number of attempts at catheterization. Catheters should therefore be changed only on the development of a complication[21].

Central venous catheters may be changed by replacement at a new site or by exchange over a guidewire[13]. The use of a different site avoids the risk of placing the new catheter through a colonized wound or of transferring intraluminal organisms to the new catheter by contaminating the guidewire in the course of the exchange. The technical complications of a catheter placed by new puncture are increased fourfold (8·8 *versus* 2·2 per cent) over those of exchange over a guidewire[20,22]. The present data show no difference in rates of catheter-related sepsis and of site infection for lines changed by either technique. Change of central venous catheters over a guidewire is therefore safe[23] provided the line is removed if subsequent investigation proves that catheter-related sepsis is present.

Announcement

European Surgical Fellowships

The Council of *The British Journal of Surgery* is pleased to announce the availability of European Surgical Fellowships for 1994. Last year four Fellowships were awarded, to Dr Jose Luis Aguayo-Albasini (Spain), Mr R. M. Charnley (Nottingham), Mr S. D. Heys (Aberdeen) and Mr T. G. John (Edinburgh).

It is Council's intention to offer European Surgical Fellowships again in 1994. Each Fellowship will have a value of up to £3000 and is intended to allow surgeons working in the UK to visit centres in other European countries or surgeons working in other European countries to visit the UK. Applicants must be under 40 years of age and should submit details of their proposed itinerary and its anticipated cost, together with a copy of their *curriculum vitae* and two letters of support from senior colleagues. They should explain briefly how such a visit might broaden their experience and assist their career. Fellowships will not be awarded solely for the purpose of attending courses or meetings.

Applications should be sent to the Company Secretary, Professor D. C. Carter, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, by 1 February 1994.

On-scene medical decision making and overtriage

T. J. Coats, A. W. Wilson and F. W. Cross

Helicopter Emergency Medical Service, The Royal London Hospital Trust, Whitechapel Road, London E1 1BB, UK

Correspondence to:
Mr T. J. Coats

This study examined whether a hospital-based helicopter trauma service led to 'overtriage' of patients back to the multispecialty base hospital. All accident-site triage decisions made during 1991 were studied. Seven of the 574 decisions (1·2 per cent) led to inappropriate movement of the patient to a specialist centre. Twenty-six decisions (4·5 per cent) were based on mechanism of injury alone and the possibility of overtriage by this method is discussed. A trained doctor can select the correct destination for a patient with trauma without inappropriately using the base hospital in preference to local centres.

Considerable benefit is gained by transporting the trauma patient directly from the accident scene to a hospital with the necessary specialist facilities for treating major injuries rather than to the nearest hospital[1]. Doctors involved in prehospital care have the opportunity to make decisions regarding the optimum hospital destination. This triage is most important in urban areas, where there may be large numbers of accident and emergency units in close proximity with a varying range of associated specialties. Factors important in correct triage are: (1) mechanism of injury; (2) the patient's physiological state; (3) the injuries themselves; (4) specialist facilities available in each of the nearby hospitals; and (5) likely transport times.

The initial protocol for the Helicopter Emergency Medical Service (HEMS) operation intended that severely injured patients would be picked up from anywhere within the four Thames Regions[2]. Patients were transported to the nearest hospital with appropriate facilities to treat their injuries, a decision taken at the incident scene by the HEMS registrar. This study was designed to assess whether triage decisions at the scene led to unnecessary transport to a specialist centre.

Many American trauma systems use triage protocols to enable paramedics to decide hospital destination. Coding of initial clinical observations, mechanism of injury and site of apparent injuries[3–6] has led to the development of a large number of methods such as the Trauma Score[7], the Triage Revised Trauma Score[8], the CRAMS (circulation, respiration, abdomen, motor and sensory) score[9], the Pre-Hospital Index[10], the Revised Trauma Index[11] and the Trauma Triage Rule[12,13]. Details of these protocols vary, but most result in patients with the following criteria being transported to a trauma centre:

1. High-speed (>40 m.p.h.; > 65 km/h) moving vehicle accident.
2. Pedestrian hit by vehicle at more than 20 m.p.h. (30 km/h).
3. Ejection from vehicle.
4. Fall from height >20 feet (6 m).
5. Penetrating injury to head, neck, chest, abdomen, pelvis or groin.
6. Blunt injury with significant involvement of head, neck, chest, abdomen or pelvis.
7. Two or more proximal long bone fractures.
8. Blood pressure <100 mmHg.
9. Respiratory rate >29 or <10 per min.
10. Glasgow Coma Score (GCS) ⩽10.

Failsafe protocols are considered vital in America to ensure that patients are 'overtriaged' to trauma centres[14]. This practice reduces the overall mortality rate[15], but many of these referrals are unnecessary[16–18] as patients often have only minor trauma despite a severe mechanism of injury[19]. The judgement of American ambulance personnel may be as effective as scoring systems in selection of the seriously injured[20]. The involvement of a doctor leads to selection of a group of patients with significantly higher median Injury Severity Score (ISS)[21]. These American criteria, developed for use by paramedics, may not be ideal for decision making when an early assessment is made by an appropriately trained doctor, especially in the context of London's extensive supply of accident and emergency departments.

Medical decision making was examined to assess triage at the incident scene, analyse the factors essential in the choice of hospital destination and determine whether overtriage to the base hospital took place.

Patients and methods

Prehospital notes of all patients attended by HEMS during 1991 were examined, and the nearest hospital and receiving hospital recorded. If the patient was not taken to the nearest hospital, the initial observations and Abbreviated Injury Score (AIS) for each body area were recorded.

The registrars in the helicopter service are provided with a computer-generated specialty specification of the hospital nearest to any incident attended. The nearest burns unit, neurosurgical unit and multispecialty hospital are also given. The specialties are matched against the patient's injuries and, with local knowledge from ambulance crews about traffic conditions and possible obstructions, the treatment centre is chosen. A triage decision to transport the patient away from the nearest hospital was considered correct in the following circumstances:

1. GCS <12 with no neurosurgery unit at the nearest hospital.
2. Burns >15 per cent with no burns unit at the nearest hospital.
3. Severe chest injury (chest AIS ⩾3) with no cardiothoracic unit at the nearest hospital.
4. Severe facial injury (face AIS ⩾3) with no maxillofacial unit at the nearest hospital.
5. Spinal injury (spine AIS ⩾3) with no specialist unit at the nearest hospital.
6. If the HEMS registrar recorded logistic reasons, such as: (a) the travelling time was significantly less by air than by land; (b) the patient was being airlifted from an inaccessible position when the local hospital had no landing site; or (c) there was a barrier such as traffic, roadworks, or accident debris preventing access to the local hospital, and the local hospital had no helipad.

Patients who did not fall into these categories were examined and outcome recorded.

Results

Of 574 patients assessed by the HEMS registrars, 373 (65 per cent) were triaged to the local accident and emergency department; 104 (18 per cent) of these patients had injuries severe enough to warrant medical escort by the HEMS doctor. Of the 201 patients (35 per cent) taken to a hospital that was not the nearest to the incident scene, 161 (28 per cent) were transferred to the multidisciplinary centre at the Royal London

0007-1323/93/101291-03 © 1993 Butterworth-Heinemann Ltd

Hospital and 40 (7 per cent) to other specialist centres (*Figure 1*).

Reasons for the triage decisions in the 201 patients not taken to the hospital nearest to the incident scene are shown in *Table 1*. Three of the four patients who were incorrectly triaged had severe head injuries and were moved to the Royal London Hospital, although the local hospital had neurosurgical specialists. The fourth patient had suffered a gunshot wound to the left groin and was incorrectly triaged in the misplaced belief that local traffic difficulties would prevent immediate transfer to a closer centre by road.

Twenty-six patients (4·5 per cent) were transported to specialist centres because of the mechanism of injury; one of these died. The ISSs for these patients are shown in *Figure 2*. No data were available for three patients as injury severity scoring was not performed at the centres to which they were taken.

GCS, Glasgow Coma Score; AIS, Abbreviated Injury Score

Discussion

It is known that taking a patient direct to the appropriate specialist centre leads to the best outcome[22,23]. The 148 patients in the present study with burns or head, chest, facial or spinal injury taken to the appropriate specialist centre are therefore not discussed further.

Three patients (0·5 per cent) were thought to require specialist treatment (two with spinal and one with thoracic injury) but were subsequently found not to have severe trauma (AIS ≤ 2). In retrospect, a further four (0·7 per cent) of the triage decisions were incorrect because the local hospital had all the facilities to treat the injuries and there was no logistic reason why transport to the nearest hospital should have been difficult. The only death in this group was from a severe head injury (AIS 5).

For 26 patients (4·5 per cent), the decision to transport to a specialist centre was based on mechanism of injury. The only death in this group followed blood loss in a patient with multiple fractures who refused transfusion on religious grounds. Only seven of these patients had severe injuries (ISS > 16) and none needed facilities not available in the local hospital. Mechanism of injury appears to be only 25 per cent specific for severe trauma in patients who are fully conscious with no initial haemodynamic or respiratory compromise and does not predict those requiring specialist treatment. In the only comparable series[24], an Italian helicopter medical team, using triage decisions heavily weighted for mechanism of injury, had an overtriage rate of 38 per cent. The present series, however, is too small to refute the large body of evidence supporting the importance of mechanism of injury[25]. The 26 patients moved on the basis of mechanism of injury were therefore triaged correctly according to protocol. In retrospect they may not have been appropriate patients for a multidisciplinary centre. In Britain it is not yet known whether patients with ISS > 16 who do not need specialist intervention (i.e. have a combination of orthopaedic and general surgical injuries) benefit from transport direct to a multidisciplinary centre, and no definite statement can be made as to whether these patients were overtriaged. There was a small bias towards moving the patient to a multidisciplinary centre rather than to a potentially inappropriate local hospital; this acts in the patient's best interests as there is no evidence of harm resulting from inappropriate movement to a specialist centre. In contrast, an inappropriate primary journey to a non-specialist hospital could result in long delays and possible secondary transfer before definitive intervention, with poor patient outcome[26].

Information about undertriage, i.e. patients taken to the local accident and emergency department when direct transport to a specialist centre would have been more appropriate, will not be available until the formal report on HEMS from the assessment team at the University of Sheffield. Such data are required for full analysis of triage criteria[27].

In spite of tensions and anxieties associated with medical intervention at the accident site, appropriately trained medical staff were able to triage patients effectively and, on medical criteria, inappropriately moved patients to the base hospital in only 1·2 per cent of missions. The use of mechanism of injury as a triage tool in the selection of patients for transfer to a specialist centre raised the overtriage rate to 5·7 per cent but this is likely to be in the patients' best interests.

Accident-site triage by an appropriately trained doctor, in conjunction with information from local ambulance crews, selects patients who will benefit from transport directly to a facility specializing in trauma management without significant inappropriate movement of those who could have been managed locally.

Blood loss is a major problem in the management of patients with burns treated by early excision and grafting. Acute normovolaemic haemodilution has been successfully used in cardiac surgery for many years but has not been reported previously in surgery for burns. The technique has been used in six patients with burns undergoing early excision and grafting, with no obvious morbidity and an apparent reduction in homologous blood requirements.

The advantages of early tangential excision and split-skin grafting for deep dermal and full-thickness burns are well established, particularly with regard to reduction in the length of hospital stay[1]. Blood loss associated with this technique may limit the extent of surgery to excision of between 10 and 30 per cent of body surface area burn, depending on whether tourniquets can be used[2]. The morbidity of homologous blood transfusion is well documented and new risks are constantly being identified[3,4]. Children are at particular risk because of their long expected lifespan after transfusion[5]. They also form the majority of patients suitable for early burn excision and grafting.

Acute haemodilution has been widely practised in cardiac surgery for over 20 years but, despite its increasing use in vascular and general surgery, has not previously been applied to surgery in the treatment of burns.

Patients and methods

Hospital Ethics Committee approval was gained for the study protocol and written consent obtained from the patient or guardian before surgery. Patient selection was based on a likely need for blood transfusion and the guidelines for autologous transfusion issued by the Blood Transfusion Task Force of the British Committee for Standards in Haematology[6]. The final decision on whether to proceed with harvest was made by the consultant anaesthetist (P.T.) and surgeon (F.B.B.). Monitoring included electrocardiography, measurement of blood pressure (using a cuff or direct measurement) and central venous pressure, and pulse oximetry. The volume of blood to be harvested was calculated as 10 ml/kg with monitoring by use of serial haematocrit measurements.

Blood harvest was started only when the patient was anaesthetized and awaiting surgery. An initial on-table haematocrit of at least 30 per cent was required before proceeding. Blood harvest and samples were taken from a central venous line with the patient in a 10° head-down position. The volume of blood harvested was replaced over 5 min with a similar volume of Hartmann's solution and the haematocrit remeasured. If the haematocrit was still greater than 30 per cent, further blood was harvested as necessary.

Surgery then proceeded and the harvested blood was returned when 10 per cent of circulating blood volume had been lost during operation. All the autologous blood was restored by, or shortly after, completion of surgery; any further requirements were satisfied using homologous blood. Prior consent was obtained to dispose of the harvested blood should any contraindication to its reinfusion have arisen. The only additional facilities required were a dedicated supervisor for the harvest and the taking of samples for haematocrit measurements, and the presence of a pressurized bag of Hartmann's solution, connected to the central line, for infusion in the event of sudden circulatory collapse.

Results

Details of the patients studied are given in *Table 1*. Observations of pulse, blood pressure and central venous pressure in all six were within 10 per cent of reference values throughout the procedure. After the first two patients, harvesting of the blood and volume replacement added approximately 15 min to the duration of the procedure.

Table 1 *Patient details*

Patient no.	Age (years)	Sex	Burn type	Burn site	Body surface area (%)	Area excised (cm²)
1	11	M	Flame	Upper arm	4	360
2	21	F	Contact	Trunk	3	550
3	23	M	Contact	Arm	6	550
4	13	M	Flame	Hands, legs	30	2510
5	30	F	Scald	Trunk	18	1060
6	48	M	Flame	Trunk, legs	45	1520

Estimated blood loss, autologous and homologous transfusion volumes, and the calculated and actual changes in haemoglobin concentration during the perioperative period are given in *Table 2*.

Blood volume calculations were based on a blood volume of 75 ml/kg, with the exception of patients 2 and 5, who were both female with a significant covering of body fat and in whom a volume of 70 ml/kg was used. Patients 5 and 6 required homologous transfusion (2 and 4 units red cells respectively).

Expected postoperative haemoglobin concentrations were calculated as the difference between the total haemoglobin lost and the total at the start of the procedure as a concentration in the blood volume calculated from body-weight. Patient 2 had a higher haemoglobin concentration on admission (14·4 g/dl) and slight haemodilution may have occurred after induction of anaesthesia, resulting in the postoperative haemoglobin level being above the immediate preoperative value and the large operative 'gain'.

No intraoperative or postoperative complications were observed.

Discussion

There is a definite, albeit low, morbidity associated with homologous blood transfusion and it is therefore desirable to minimize or avoid such transfusion when possible[3,4]. Acute haemorrhage induces hypercoagulability, which homologous transfusion is reported to diminish[7]. This may be of significance in surgery for burns, where blood loss results from widespread oozing from a large number of capillaries rather than from a small number of larger vessels. Other factors influencing the indications for homologous transfusion are the acceptable haemoglobin level, the timing of transfusion and the availability of the patient's own red cells.

There has been much debate on the acceptable concentration of haemoglobin, but most investigators consider levels of between 8 and 9 g/dl to be safe[8]. Rush *et al.*[9] confirmed the reliability of changes in the haematocrit as an index for

replacement of blood with electrolyte solutions and its usefulness in providing an endpoint for beginning the use of blood.

Autologous blood may be obtained from three sources. Elective predonation is not applicable to early surgery for burns, and intraoperative and postoperative cell salvage is considered hazardous when the blood has been exposed to bacterial contamination[10].

Acute haemodilution with harvesting of 25–30 per cent of the patient's blood volume has become established practice in cardiac surgery after an initial report[11] in 1968. A literature search has revealed no previous reports of the use of this method in early surgery for burns. Acute haemodilution has now been safely undertaken in such patients in a controlled situation with no obvious morbidity in this small number. The majority of patients undergoing surgery for burns are young, with many years to develop the complications of homologous transfusion[12]. Used in combination with methods of reducing blood loss and requirements, acute haemodilution could enable the avoidance of homologous transfusion in many of these patients.

Acknowledgements

The authors acknowledge the assistance and support received from the Blood Transfusion Service at national (Scottish), regional and local levels. The assistance of Professor A. Aitkenhead (Head of the Department of Anaesthetics, University of Nottingham) in the preparation of the manuscript is appreciated.

Suppression of cellular immunity following thermal injury may contribute to the high incidence of postburn sepsis. Early excision and skin grafting may remove deleterious local wound factors and prevent immunosuppression. The effect on cellular immunity of early burn wound excision and skin grafting was investigated in an animal model using female Wistar rats. The development of immunosuppression shortly after burn injury was shown by popliteal lymph node assay and a 2,4-dinitrofluorobenzene skin reaction test. Excision and skin grafting 2 days after burn trauma restored parameters to normal. Burned tissue suppresses cellular immunity; this effect is preventable by early excision and skin grafting.

Patients exhibit a wide variety of immunological changes following thermal injury. Impaired neutrophil function, a reduced T helper:T suppressor ratio, decreased lymphocyte blastogenesis in response to mitogens, impairment of interleukin 2 production and the presence of circulating suppressive factors have been implicated in the pathophysiology of immunodepression related to burn injury[1–9].

Since the early work of Meeker and Snyder[10] the beneficial effects on morbidity and mortality rates of early excision and skin grafting have been reported[11–14]. There are, however, few *in vivo* controlled studies evaluating cellular immunity following early excision and skin grafting. The present study examined the effect of early excision and grafting on popliteal lymph node assays and 2,4-dinitrofluorobenzene skin reaction tests as measures of cellular immune competence.

Materials and methods

Animals and surgical techniques

Female Wistar rats weighing 180–200 g were caged in groups of three at ambient room temperature, and given water and food *ad libitum*. After acclimatization for 1 week the animals were randomized to four groups: sham-burned controls (group 1), burned (group 2), burned with early excision and skin grafting (group 3), and excision and skin grafting without burn injury (group 4). Group 1 comprised ten animals that were anaesthetized and shaved but not scalded. Group 2 animals ($n = 72$) were randomized into six subgroups of 12 each to study responses on days 1, 4, 7, 10, 14 and 21 after burn. Group 3 rats ($n = 60$) underwent early excision and skin grafting at 48 h. Animals in this group were randomized into five sets of 12 to evaluate immune responses on days 4, 7, 10, 14 and 21 after thermal injury. On the designated days for each group, wounds were completely excised and the defects closed with a split-thickness graft from a Lewis rat. Group 4 consisted of ten rats that were not given thermal injury but underwent the same percentage skin excision and grafting.

Burn model

Animals were anaesthetized with pentobarbital 45 mg kg^{-1}. The back and abdomen were shaved. The rats were placed in a mould that left 30 per cent of the total body surface area exposed and this surface immersed into a water bath at 95°C for 10 s. Animals were then resuscitated with Ringer's lactate solution 6 ml intraperitoneally.

Contact hypersensitivity

Rats were sensitized by the application of 100 μl 0·5 per cent 2,4-dinitrofluorobenzene (Sigma Chemicals, St Louis, Missouri, USA) in 4:1 acetone:olive oil on the shaved abdomen on days 1, 4, 7, 10, 14 and 21 after burn. Some 5 days later the animals were challenged by application of 2,4-dinitrofluorobenzene to the ears. Ear swelling was measured using calipers after 24 h and the results expressed as a percentage of swelling in controls (group 1).

Popliteal lymph node assay

This was accomplished using a previously described method[15]. Splenocytes from Sprague–Dawley rats were given to Wistar recipients for the host *versus* graft reaction. Splenocyte suspensions were prepared by mincing the pulp into a balanced salt solution. Erythrocytes were lysed with Tris–NH_4Cl. Suspensions were washed twice and the cells resuspended in balanced salt solution to a concentration of 20×10^7 viable cells per ml (trypan blue exclusion assay). In 0·1 ml, 20×10^6 viable cells were injected into the right hind footpad of the recipient. After 5 days the recipients were anaesthetized and the popliteal lymph nodes from both hind legs removed and weighed. Popliteal lymph node enlargement in response to antigenic challenge in each recipient was evaluated using the ratio of injected to uninjected node weight.

Statistical analysis

Data are presented as mean(s.e.m.). Statistical significance was assumed at $P < 0·05$ and determined by Student's t test.

Results

A total of 23 rats (17·4 per cent) died within 72 h after injury; sham burn, and early excision and skin grafting without previous burn injury resulted in no mortality. Clearly demarcated full-thickness third-degree burn eschars were obtained within 48 h. These then gradually sloughed in 15–25 days. The wounds did not become grossly infected and healed over a 3–4-week period by contraction and skin growth from the wound edges.

Compared with normal controls (group 1) the mean(s.e.m.) contact hypersensitivity response to 2,4-dinitrofluorobenzene in group 2 (97·1(1·1) per cent) was inhibited by burn injury. The mean(s.e.m.) ear swelling was significantly reduced in response to application of 2,4-dinitrofluorobenzene on days 7 (33·5(2·9) per cent) and 10 (20·0(4·3) per cent) ($P < 0·001$). By 21 days after burn the wounds were largely healed in most animals and response to 2,4-dinitrofluorobenzene (89·4(5·0) per cent) had returned to nearly normal levels.

Early wound excision and skin grafting at 48 h after burn injury improved response to 2,4-dinitrofluorobenzene in group 3 to levels comparable to those of controls. Waiting more than 48 h before early excision and skin grafting resulted in a decreased improvement (*Figure 1*); deterioration in immune status was directly proportional to the waiting period. The contact hypersensitivity response in this group returned to normal levels on day 21 after thermal injury. Immunosuppression as measured by the 2,4-dinitrofluorobenzene skin test was minimal (mean(s.e.m.) 91·4(4·6) per cent) in group 4 animals.

The mean popliteal lymph node weight in uninjected controls was 41·2 mg. Following the injection of splenocytes

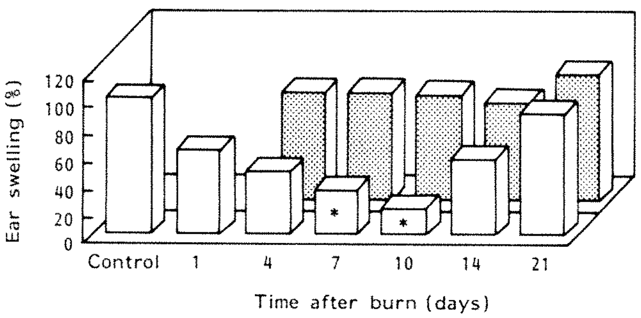

Figure 1 *Mean contact hypersensitivity reaction to 2,4-dinitrofluorobenzene at different times after burning.* □, *30 per cent burn injury;* ▨, *30 per cent burn injury with early excision and skin grafting.* *$P < 0\cdot001$ (*days 7 and 10* versus *controls, Student's* t *test*)

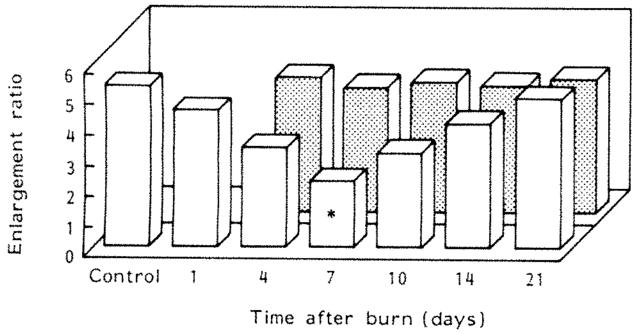

Figure 2 *Popliteal lymph node assay. Enlargement following standard injection of spleen cells is expressed as the mean ratio of the weight of injected to uninjected nodes.* □, *30 per cent burn injury;* ▨, *30 per cent burn injury with early excision and skin grafting.* *$P < 0\cdot001$ (*day 7* versus *controls, Student's* t *test*)

the peak mean(s.e.m.) enlargement ratio in unburned rats (group 1) was found to be 6·0(1·0). This value was indicative of severe immunodepression, which became worse at day 7 (2·2(0·3)) ($P < 0\cdot001$) in burned group 2 rats. Immediate early excision and skin grafting after burning in group 3 resulted in a return of the popliteal lymph node assay response toward normal levels, although the values remained reduced from those of group 1 (*Figure 2*). No significant immunodepression was demonstrable in group 4: at 4, 7, 10, 14 and 21 days after thermal injury the respective mean(s.e.m.) enlargement ratios were 4·5(0·9), 4·1(0·7), 4·3(0·3), 4·2(0·3) and 4·5(0·7).

Discussion

Thermal injury leads to an immunosuppressed state and renders the burned host more susceptible to sepsis[8,16,17]. The pathophysiology of postburn immunosuppression involves specific cellular and humoral defects[2,9]. Removal of either the burn wound or cellular elements of the immune system from the burned host improves cellular immune function[18–20]. These findings suggest that the burn wound might be the major factor responsible for immunosuppression after thermal injury. Delayed-type skin reaction tests and popliteal lymph node assay are accepted methods for quantitative *in vivo* monitoring of immune status. The contact hypersensitivity skin test has been shown in previous experiments[21,22] to be a sensitive and quantifiable measure of cellular immunity. The popliteal lymph node assay is an established method that reflects *in vivo* mixed lymphocyte reactions and permits the evaluation of host *versus* graft responses[20,22,23].

The results of the present study indicate that immune function gradually deteriorates beginning from day 1 after burning and reaching a trough between days 7 and 10. Immune function then gradually returns to normal levels, becoming almost normal on day 21. During this period diminished immune responsiveness measurable by popliteal lymph node assay and 2,4-dinitrofluorobenzene skin test was not accompanied by any gross quantitative cellular abnormality. These findings are in agreement with previous reports[9,24] but contrary to the results of Piacentine *et al.*[22], who found maximal immunosuppression to occur on day 14 after burning.

Numerous human studies favour early aggressive wound excision and skin coverage[10,12–14]. Controlled prospective trials in humans are difficult because of the presence of many variables (e.g. age, sex, extent of injury) and ethical issues.

Full-thickness burns of 20 per cent total body surface area are necessary for detectable immunosuppression[25]. Using such models of burn injury leads to increased suppressor T cell activity[8], a decreased helper:suppressor T cell ratio[26], diminished delayed hypersensitivity[20,22,27], a decreased lymphocyte blastogenesis response[28] and increased susceptibility to infection[9,29].

The present experiments simultaneously investigated the effect of burn, early excision and skin grafting, and burn with early excision and grafting on immune responsiveness. The degree of immunosuppression following burn with early excision and skin grafting was not significantly different from that observed in groups 1 and 4. This indicates that immunosuppression in group 3 most probably related to the effect of early excision and skin grafting itself. This is supported by previous data on the immunosuppressive effect of early excision and skin grafting, and other operations without preceding burn injury[30,31].

The continued presence of burned tissue is a major aetiological factor for immunosuppression that can be avoided by early excision and skin grafting.

The records of 15 women presenting with axillary nodal metastases from an occult primary consistent with breast carcinoma were reviewed. Nine patients underwent complete axillary clearance and in six the clinical mass only was excised. Radiotherapy to the axilla was given to eight patients. One woman underwent mastectomy at the time of axillary surgery but no tumour was found in the excised breast; in the remaining 14 patients the breast was left untreated. One premenopausal woman received adjuvant systemic chemotherapy and one postmenopausal patient was given tamoxifen. Three patients died from recurrent disease at 16, 50 and 56 months after treatment of the axillary mass; one is alive at 42 months with systemic recurrence. In two of these patients the tumour in the breast became apparent before other metastases. Eleven patients survived for a median of 92 (range 18–144) months without evidence of disease. The prognosis of this patient group is better than that generally reported for stage II breast carcinoma.

The metastatic enlargement of axillary lymph nodes may be the first sign of occult carcinoma of the breast[1,2]. Treatment has consisted of axillary surgery and mastectomy[1,3–7] but in a number of patients the primary tumour was not found in the breast specimen. Two recent studies demonstrated that patients treated with radical radiotherapy to the breast have the same prognosis as those who undergo mastectomy[2,6]. When the breast is left untreated the survival rate of the patients does not decrease[2,5,7,8]. In the present report, 15 women presenting with axillary nodal metastases from an occult primary consistent with breast carcinoma are described; in 14 the breast was left untreated.

Patients and methods

Between July 1980 and February 1991, 15 women were referred with a diagnosis of metastatic adenocarcinoma of the axilla from an unknown primary site. The histopathological findings of all axillary masses were consistent with breast carcinoma. On initial clinical examination none of the patients had a distinct palpable primary breast mass. One woman had undergone lumpectomy 3 months previously but review of the histopathology confirmed the diagnosis of a benign breast lesion. All patients underwent mammography and in two a suspicious lesion was seen. Localization biopsy, however, demonstrated benign lesions.

Many investigative procedures were carried out in 11 of the 15 patients in an attempt to find the primary tumour. In four patients only mammography, chest radiography, liver ultrasonography and bone scintigraphy were performed. In three patients ipsilateral supraclavicular node metastases were noted concurrently. In two patients contralateral breast carcinoma had been treated 8 and 11 years before the present axillary mass. One of these patients had been treated by lumpectomy, axillary clearance and irradiation of the breast (45 Gy, iridium boost 25 Gy) and parasternal area (45 Gy). The other had been treated by simple mastectomy and axillary clearance followed by irradiation of the parasternal area (45 Gy). Both tumours were classified as $pT_1 N_0$. One patient with a diagnosis of stage I malignant lymphoma in the right groin had been treated with irradiation and chemotherapy 3 years before presentation with adenocarcinoma of the axillary node.

Local treatment

Axilla. Nine patients underwent complete axillary clearance with the specimen containing a median of 2 (range 1–6) metastatic lymph nodes. In six patients the clinical mass only was excised. Additional radiotherapy to the axilla and supraclavicular area was given to eight patients (five of nine after axillary clearance, three of six after local excision). Radiation therapy was given with megavoltage equipment using standard techniques: four doses of 50 Gy and four of 40·5 Gy were delivered. In three patients a booster dose of 20 or 30 Gy was given for supraclavicular lymph node metastasis. One patient with five positive nodes in the axillary specimen was offered radiation therapy but refused.

Breast. Only one patient underwent mastectomy but no tumour was found in the breast. One of the patients received radiation therapy to the breast.

Adjuvant systemic treatment

One premenopausal patient (one positive node of 15) received systemic chemotherapy with five cycles of cyclophosphamide, methotrexate and 5-fluorouracil, and refused the sixth cycle. One postmenopausal patient received adjuvant treatment with tamoxifen.

Clinical and follow-up data were complete for all patients.

Results

The 15 women had a median age of 54 (range 36–72) years. All axillary masses contained adenocarcinoma and in seven patients this was poorly differentiated, consistent with a primary in the breast. Four patients had moderately well differentiated metastatic adenocarcinoma and four unclassified lesions.

Three patients died from recurrence at 16, 50 and 56 months after treatment of the axillary mass; one is alive at 42 months with recurrent disease of the liver and contralateral axilla. Two of these patients presented with supraclavicular node metastases. In two patients the tumour in the breast became detectable (clinically and mammographically) after 10 and 31 months of follow-up, but before other metastases. Treatment of these tumours consisted of simple mastectomy in one patient and lumpectomy with radiation therapy of the breast in the other.

Eleven patients have a median survival time of 92 (range 18–144) months without evidence of disease. In two of these contralateral breast carcinoma developed at 33 and 60 months; these cancers were treated by lumpectomy, axillary clearance and irradiation to the breast. The tumours were ductal cancers (not otherwise specified) with classification $pT_1 N_0$.

Discussion

The frequency of occult breast carcinoma presenting with regional lymph node metastasis is difficult to determine but it may account for less than 0·45 per cent of primary operable breast cancer[1,3,9]. Apart from breast primaries many other adenocarcinomas may metastasize to axillary nodes[3,10], but in the absence of localized signs or symptoms there is little value in exhaustive evaluation attempting to find a primary tumour[1,3]. The present use of immunohistochemistry, oestrogen receptor analysis, cytogenetics and flow cytometry may strengthen the diagnosis of metastatic breast cancer[3,11], although a negative receptor result on lymph node biopsy does not rule out a breast primary.

Mastectomy with complete axillary clearance has been the recommended treatment for patients presenting with axillary lymph node metastases consistent with a breast primary[1-3]. Examination of the excised breast disclosed cancer in 8-82 per cent of patients[1,2,4,5,7,8]. Many of these patients, however, were treated at a time when mammography or localization biopsy may not have been available[1,4,7].

Two recent studies demonstrated that patients treated with radiotherapy to the breast have the same prognosis as those who undergo mastectomy[2,6]. In the present study the breast was left untreated in 14 of the 15 patients. At a median follow-up of 7·5 years carcinoma developed in the breast of two patients. This local failure rate is lower than those reported by Ellerbroek *et al.*[2] and Merson and colleagues[8] in comparable groups of patients, and even lower than the 19-27 per cent observed in patients treated with radiotherapy[2,6]. The progression-free survival rate of the whole of the present group was 73 per cent at a median follow-up of 7·5 years and survival thus seems not to be hampered by withholding immediate therapy to the breast. This is in concordance with the experience of others[2,8].

The availability of modern mammographic equipment allows the option of withholding definitive local therapy until clinical or radiographic appearance of the primary tumour. The axilla should preferably be treated by axillary clearance[12], although when supraclavicular node disease is present simultaneously the indication for axillary clearance is less convincing. The role of radiotherapy and adjuvant chemotherapy or hormonal therapy is to provide the same treatment for these patients as for those with a known breast primary and similar nodal stages. This means that at present all patients should receive systemic therapy with either combination chemotherapy or antihormone treatment[13].

Patients with axillary metastases histologically consistent with breast cancer should be treated identically to those with the same features and a proven breast primary. A 'wait and see' policy towards the breast may be warranted and an extensive search for an extramammary primary tumour in the absence of signs and symptoms is not useful.

Topkapı, İstanbul, Turkey

Between 1986 and 1991, thyroidectomy was performed on 138 patients with hyperthyroidism. Thyroid carcinoma was found in eight patients (5·8 per cent). Eighty (58·0 per cent) of the 138 patients had toxic nodular goitre, 33 (23·9 per cent) toxic diffuse goitre and 25 (18·1 per cent) toxic adenoma. Concurrent carcinoma was more frequent in patients with toxic adenoma (8 per cent) than in those with Graves' disease (6 per cent) and toxic nodular goitre (5 per cent). Papillary carcinoma was found in seven patients and follicular carcinoma in one. Three papillary carcinomas were occult with a diameter less than 1·5 cm. Five patients received 100 mCi ^{131}I after operation. There was no morbidity. During follow-up of 10–45 months, there was neither death nor recurrence.

Thyroid carcinoma in patients with hyperthyroidism was first reported by Sokal[1] in 1954; it was observed that the incidence was 20-fold higher in those with thyrotoxicosis than the euthyroid state. Widely differing coincident frequencies (0·76–8·7 per cent) have been reported[1,2]. The possible coexistence of carcinoma, especially in patients with toxic nodular goitre, suggests that surgery is the preferred treatment[3]. In the present retrospective study, eight patients with concurrent hyperthyroidism and thyroid carcinoma were reviewed.

Patients and methods

Between 1986 and 1991, thyroidectomy was performed on 138 patients for hyperthyroidism. Eighty (58·0 per cent) had toxic nodular goitre, 33 (23·9 per cent) toxic diffuse goitre and 25 (18·1 per cent) toxic adenoma. Thyroid carcinoma was found in eight patients (5·8 per cent): four (5 per cent) with toxic nodular goitre, two (8 per cent) with toxic adenoma and two (6 per cent) with Graves' disease. During the same period, carcinoma was found in 66 (6·9 per cent) of 958 patients undergoing thyroidectomy.

The eight patients were seven women and one man of age 19–65 (mean 43·1) years. All patients were thyrotoxic at the initial clinical examination. Their symptoms and clinical features are summarized in *Table 1*. One patient had severe thyrotoxicosis associated with rapid enlargement of the gland. Laboratory investigation confirmed thyrotoxicosis in all patients. Clinical and radioisotope scan results are shown in *Table 2*. Propylthiouracil or methimazole was used before operation in all patients; the duration of therapy ranged from 3 to 12 months. None of the patients was suspected of having carcinoma before or during operation. Subtotal thyroidectomy was performed in six patients, near-total thyroidectomy in one and total thyroidectomy in one.

Presented at Eurosurgery 92 in Brussels, Belgium, June 1992 and published in abstract form as Br J Surg *1992;* **79***: S42*

Results

Of six patients in whom subtotal thyroidectomy was performed, three had occult papillary carcinoma. Of the remaining three patients, two were found to have papillary carcinoma and one follicular carcinoma. In these three patients ablation with radioactive iodine was used to eradicate the disease as the remnants were very small.

Follicular carcinoma was found in one patient with severe thyrotoxicosis associated with rapid enlargement of a goitre and a scan demonstrating a solitary hot nodule. The patient who underwent near-total thyroidectomy had papillary carcinoma confined to one lobe. Sclerosing papillary carcinoma was found in both lobes in the patient undergoing total thyroidectomy. In three patients with papillary carcinoma, histological localization of the tumour corresponded to areas

Table 1 *Details of patients*

Patient no.	Age (years)	Sex	History	Clinical examination
1	56	F	Slow enlargement of goitre for 4 years Symptoms of thyrotoxicosis for 1 year	Mild thyrotoxicosis; bilateral multinodular goitre
2	52	F	Slow enlargement of goitre for 3 years Symptoms of thyrotoxicosis for 1 year	Mild thyrotoxicosis; bilateral hyperplasia; nodule in left lobe
3	43	F	Slow enlargement of goitre for 25 years Symptoms of thyrotoxicosis for 1·5 years	Moderately thyrotoxic; bilateral multinodular goitre
4	40	F	Slow enlargement of goitre for 20 years Symptoms of thyrotoxicosis for 8 months	Mild thyrotoxicosis; bilateral hyperplasia; nodule in left lobe
5	65	F	Rapid enlargement of a nodule Symptoms of thyrotoxicosis for 1 year	Severe thyrotoxicosis; large nodule in right lobe
6	42	F	Slow enlargement of goitre for 17 years Symptoms of thyrotoxicosis for 3 months	Moderately thyrotoxic; one nodule in left lobe, one nodule in right lobe
7	19	F	Slow enlargement of goitre for 4 years Symptoms of thyrotoxicosis for 3 months	Moderately thyrotoxic; bilateral diffuse hyperplasia
8	28	M	Slow enlargement of goitre for 1 year Symptoms of thyrotoxicosis for 8 months	Moderately thyrotoxic; bilateral diffuse hyperplasia

0007-1323/93/101301-02 © 1993 Butterworth-Heinemann Ltd

Table 2 *Radioisotope scan, operative and histological findings*

Patient no.	Radioisotope scan	Operative findings	Histological findings
1	Bilateral hyperplasia Areas of low uptake in both lobes	Bilateral hyperplasia Multiple small nodules in both lobes	Occult papillary carcinoma in left lobe
2	Bilateral hyperplasia Non-homogeneous uptake in both lobes	Bilateral hyperplasia Multiple small nodules in both lobes	Occult papillary carcinoma in right lobe
3	One cold nodule in right lobe Two cold nodules in left lobe	Cystic 10-cm nodule in right lobe Multiple small nodules in left lobe	Papillary carcinoma in right lobe
4	Bilateral hyperplasia Cold nodule in left lobe	Firm nodule in left lobe Frozen-section examination: adenomatous nodule	Papillary carcinoma in left lobe and partially in right lobe
5	Hot nodule in right lobe	Nodule of 5 cm in right lobe Multiple small nodules in left lobe	Follicular carcinoma in both lobes
6	Hot nodule in right lobe Irregular uptake in left lobe	Multiple nodules in both lobes	Occult papillary carcinoma in right lobe
7	High diffuse uptake	Bilateral diffuse hyperplasia	Papillary carcinoma in both lobes
8	High diffuse uptake	Bilateral diffuse hyperplasia	Two foci of papillary carcinoma in right lobe

of low uptake on a radioisotope scan. These results are summarized in *Table 2*.

At 4 weeks after surgery, a whole-body scan was performed in two patients and a thyroid scan in all eight. There was no evidence of local or distant metastasis. All patients were given oral thyroxine therapy. Patients received ablative doses of radioiodine, except for those with occult carcinoma.

Follow-up ranged from 10 to 45 (mean 30) months. There was no recurrence or death during this period.

Discussion

Different frequencies of concurrent hyperthyroidism and thyroid carcinoma have been reported[1–6]. The frequency of thyroid carcinoma in patients with Graves' disease was 2·5-fold greater than in those with toxic adenoma[7]. The carcinoma in patients with Graves' disease behaved more aggressively than that associated with toxic nodular goitre and toxic adenoma[7].

Based on data from 1848 patients with hyperthyroidism treated surgically, Rieger *et al.*[8] reported the incidence of coexisting malignancy as 0·76 per cent. It is remarkable that none of the 64 patients with Graves' disease had thyroid carcinoma. The authors concluded that the incidence of concurrent hyperthyroidism and malignancy was low in an endemic area of goitre. In contrast, the incidence of coexisting thyroid carcinoma and hyperthyroidism in the present study (5·8 per cent) was not much lower than that of carcinoma in euthyroid glands (6·9 per cent).

Thyroid-stimulating hormone (TSH) is thought to be the most important factor promoting growth and possibly genesis of thyroid carcinoma; differentiated thyroid carcinoma is known to contain TSH receptors. In rodents, TSH stimulation of the thyroid gland by goitrogenic diets leads to glandular hyperplasia and later neoplasia[9]. It is unclear whether human thyroid carcinoma results from excessive stimulation by TSH. Dobyns *et al.*[10] reported results of an analysis of 34 684 patients with hyperthyroidism treated with antithyroid drugs, ^{131}I, thyroidectomy, external radiation or a combination of these. The incidence of malignancy was higher in patients treated with drugs than in those receiving ^{131}I therapy or thyroidectomy and was associated with increased TSH levels.

The diagnosis of hyperthyroidism does not preclude concurrent thyroid carcinoma.

Thyroid neoplasia coexistent with chronic lymphocytic thyroiditis

R. F. McKee, Z. H. Krukowski and N. A. Matheson

Department of Surgery, University of Aberdeen, Foresterhill, Aberdeen AB9 2ZB, UK
Correspondence to:
Mr Z. H. Krukowski

During a 6-year period 115 patients presenting with thyroid enlargement had evidence of chronic lymphocytic thyroiditis on fine-needle aspiration cytology. Of 27 patients in whom histological analysis was carried out, 16 had neoplasms (follicular adenoma, four; follicular carcinoma, one; papillary carcinoma, four; lymphoma, seven). Assuming that neoplasia was not overlooked in the absence of histological examination, the overall incidence was 14 per cent and that of malignant disease 10 per cent. All patients with carcinoma had cytological features suspicious of neoplasia on the first or subsequent aspirates in addition to those of thyroiditis. Cytology was suspicious of lymphoma in only two of seven patients but increasing size of the thyroid swelling was a consistent feature. Evidence of chronic lymphocytic thyroiditis may lead to neoplasia being overlooked. Repeated cytological analysis is helpful in identifying coexistent carcinoma but unreliable in excluding lymphoma.

Chronic lymphocytic thyroiditis (Hashimoto's disease, autoimmune thyroiditis) is a common condition. In North-east Scotland (population 500000), approximately 140 patients with this diagnosis are registered annually on the Scottish Automated Follow Up Register.

The association of thyroid lymphoma with chronic lymphocytic thyroiditis is well known[1] but relatively rare. There is less awareness of the risk of other coexisting thyroid neoplasia. The typically firm or hard texture of isolated or diffuse chronic lymphocytic thyroiditis resembles that of thyroid carcinoma, but concomitant evidence of autoimmune disease (thyroid failure, raised autoantibody titre or cytological appearance) may influence the diagnosis to a degree that neoplasia is overlooked. The use of fine-needle aspiration cytology (FNAC) has heightened awareness of the frequency with which the two conditions may coexist.

Patients and methods

In the Grampian Region patients with thyroid swellings are usually referred to a joint medical–surgical thyroid clinic. Between January 1985 and December 1991, FNAC was in routine use and all patients with cytological evidence of chronic lymphocytic thyroiditis on one or more samples were studied retrospectively. Clinical characteristics, results of thyroid function tests (thyroxine, thyroid-stimulating hormone, free tri-iodothyronine), thyroid autoantibody levels, cytology, histology and management were reviewed.

Levels of thyroid autoantibodies (thyroglobulin antibody and thyroid microsomal antibody) were measured using a haemagglutination technique with a serial dilution method. Reactions at dilution levels of 1 in 100 or weaker were taken as positive.

FNAC was performed and interpreted as described previously[2]. A cytological diagnosis of chronic lymphocytic thyroiditis was based on the presence of a combination of lymphocytes, plasma cells and lymphoid follicle centre cells in association with thyroid follicular cells some or all of which showed oxyphil change (Askanazy cells, oncocytes).

The histology of all thyroid tissue removed was reviewed by a specialist pathologist.

Results

A total of 115 patients (five men, 110 women; mean age 51 (range 18–88) years) presented with thyroid enlargement and had cytological features consistent with chronic lymphocytic thyroiditis on at least one occasion. Clinically 34 patients had generalized thyroid enlargement, 60 a dominant swelling[3] within a generally enlarged gland and 21 isolated swellings. Thyroid autoantibody titres were raised in 73 patients and 44 had either clinical or biochemical evidence of thyroid failure. The combination of generalized thyroid enlargement, positive autoantibodies and thyroid failure was present in only 17 patients.

A group of 88 patients did not undergo surgery or large-bore needle biopsy and the diagnosis remained chronic lymphocytic thyroiditis.

Large-bore needle biopsy was carried out on two patients with suspected lymphoma and 25 underwent surgery. Of these 27 patients, 16 had neoplasms: follicular adenoma, four; follicular carcinoma, one; papillary carcinoma, four; and lymphoma, seven.

In 15 patients the indication for operation or large-bore needle biopsy was a combination of clinical suspicion of neoplasia with additional suspicious findings on cytology. In seven of these patients suspicion of neoplasia was raised on the first aspirate (histological findings were: papillary carcinoma, three; oxyphil follicular carcinoma, one; follicular adenoma, one; lymphoma, one; and colloid degeneration, one) and in eight patients a subsequent aspirate was reported as possibly neoplastic (histology: papillary carcinoma, one; follicular adenoma, one; lymphoma, one; and colloid degeneration, five).

Nine patients underwent operation because of clinical suspicion alone. Despite cytological evidence of chronic lymphocytic thyroiditis the isolated or dominant nature of the thyroid swelling was suspicious in four patients, two of whom proved to have follicular adenoma. Increasing size of the gland was suspicious in five patients; all proved to have lymphoma.

Of the remaining three patients, one had a dominant swelling causing tracheal compression. Cytological findings were consistent with lymphocytic thyroiditis but histology showed colloid degeneration. Two patients had a dominant swelling removed (patient preference) when there was no clinical suspicion of neoplasm; lymphocytic thyroiditis was confirmed histologically in both.

Six of the seven patients with thyroid lymphoma were women and all seven were aged more than 50 years. Apparent increase in size of the thyroid swelling, often rapid, was a consistent feature, and in five patients there was clinical and radiological evidence of tracheal compression. Results of cytology were diagnostic in one and suspicious of neoplasia in another. Histology was obtained by large-bore needle biopsy in two patients and the thyroid isthmus was resected in five

because of clinical suspicion together with tracheal compression. The histological features in these seven patients were of B cell centroblastic non-Hodgkin's lymphoma.

Discussion

Assuming that neoplasia had not been overlooked in the absence of histological analysis, 16 (13·9 per cent) of 115 patients with thyroid swelling and cytological evidence of chronic lymphocytic thyroiditis had neoplastic disease and 12 (10·4 per cent) had malignancy. The problem of neoplasia coexistent with lymphocytic thyroiditis is therefore clinically significant. The incidence in the present report is higher than commonly recorded[4,5] and reflects selection bias in a specialist clinic.

Identifying all patients with chronic lymphocytic thyroiditis is difficult because the diagnosis rests on a number of variably present factors. The classical clinical features of a hard bosselated goitre, thyroid failure and raised autoantibody titres were found in only 15 per cent of the present patients. There is also a significant incidence of raised autoantibody titres in the general population[6]. Furthermore, lymphocytic infiltration of the thyroid in asymptomatic patients[7] is common and autoantibody-negative chronic lymphocytic thyroiditis may be more prevalent than previously thought[8].

This study highlights two potential diagnostic pitfalls: the patient who has carcinoma despite evidence of chronic lymphocytic thyroiditis and the patient with coexistent lymphoma. All the patients with carcinoma or follicular adenoma presented with an isolated or dominant swelling and in all those with carcinoma cytology was reported as possibly neoplastic, in four of five cases on the first sample. Oxyphil tumours are difficult to distinguish from chronic lymphocytic thyroiditis[9] but the one such patient in the present series was identified by FNAC. Provided that clinical suspicion, despite evidence of lymphocytic thyroiditis, is maintained and cytological analysis is routine, these patients should be identified although repeated sampling is necessary.

Patients with coexisting lymphoma are more difficult to diagnose[5]. In the present study the only consistent clinical feature was increasing size of the gland, often rapid and usually associated with tracheal compression. Willems and Lowhagen[10] stated that lymphoma may be distinguished from chronic lymphocytic thyroiditis on cytology but, as described by Suen and Quenville[11], the present series demonstrated difficulties. The accuracy of FNAC in identifying lymphoma improves with experience but the method is less reliable than large-bore needle biopsy[5]. The latter may give sufficient information for the diagnosis and classification of lymphoma. The need for adequate tissue for histological classification and the frequency of tracheal compression suggest that isthmusectomy may be a diagnostic and therapeutic procedure.

Evidence of chronic lymphocytic thyroiditis in a patient with thyroid enlargement should not lead to diagnostic complacency. FNAC with repeated sampling is helpful in detecting coexistent carcinoma but unreliable in excluding lymphoma. Clinical awareness of the possibility of neoplasia is critical, particularly in detecting lymphoma.

Oesophagogastrectomy for carcinoma of the oesophagus and cardia

A retrospective review was undertaken of all oesophagectomies performed within a single unit over a 12-year period. In all, 298 patients with primary oesophageal cancer underwent resection between March 1979 and December 1991. Four patients had a three-stage oesophagogastrectomy, 27 a thoracoabdominal oesophagogastrectomy and 267 a Lewis procedure. Dysphagia was the predominant presenting symptom. The duration of symptoms was not related to the stage of disease. Before diagnosis, 52 per cent of patients tolerated symptoms for 2–4 months. Adenocarcinoma was found in 180 tumours and squamous cell carcinoma in 103. Half the patients had evidence of metastatic spread at the time of laparotomy or thoracotomy. The 30-day mortality rate was 10 per cent and the overall actuarial 5-year survival rate of all patients 23 per cent. The actuarial 5-year survival rate of patients without lymph node involvement was 39 per cent compared with 17 per cent for those with positive nodes ($P < 0.05$*). Five of eight patients who had anastomotic leakage died. The almost unselected nature of this series, coupled with the favourable results of oesophagectomy, support the contention that resection remains the preferred mode of treatment for carcinoma of the oesophagus of all histological types.*

Mr J. Rahamim

The incidence of oesophageal carcinoma is increasing in Britain[1]; this holds for both adenocarcinoma and squamous cell carcinoma[2]. However, adenocarcinoma appears to contribute a higher proportion of cancers in the UK than in most series reported from overseas[3,4]. Surgical treatment of oesophageal carcinoma in 1980 had a dismal 5-year survival rate of 4 per cent[5]. However, improved survival rates have been reported over the past decade by a number of centres[6–9]. This study reports experience with oesophagogastrectomy for carcinoma of the oesophagus performed by one surgeon in a district general hospital.

Patients and methods

A retrospective review was undertaken of all oesophagectomies performed within the Thoracic Unit at Derriford Hospital, Plymouth. In all, 298 patients with primary oesophageal carcinoma underwent resection during the period March 1979 to December 1991. This is the sole unit serving a population of 400 000–450 000, so this series is unselected. The number of oesophageal resections at this institution has increased over the years (*Figure 1*); there were 36 in 1991.

Preoperative assessment included chest radiography, abdominal ultrasonography, upper gastrointestinal endoscopy, bronchoscopy and computed tomography (CT). Resectability was assessed at laparotomy or thoracotomy and resection felt to be contraindicated if widespread infiltration of adjacent organs, or diffuse pleural or peritoneal carcinomatosis was found. Staging of oesophageal cancer was performed according to the American Joint Committee on Cancer guidelines[10]. Stage I disease was defined as tumour invading the mucosa or submucosa but not the muscularis, with no nodal or metastatic involvement. Stage II disease was limited to the oesophagus. Stage III disease included transmural involvement or lymph node metastasis (N_{0-2}). Stage IV indicated direct tumour extension to the diaphragm or pericardium, or more distant visceral metastases. Chemotherapy and radiotherapy were not given before surgery but were used occasionally after operation for palliation of recurrent or residual disease.

A variety of surgical procedures were performed depending on the location of the primary tumour. If the lesion was in the upper third of the thorax, three-stage oesophagogastrectomy was performed as advocated by McKeown[11]. Lesions of the middle and lower oesophagus were resected using a Lewis[12] procedure. In this, the most common operation in the series, end-to-side anastomosis of the oesophagus to the posterior wall of the stomach was performed using a circular stapler (Auto Suture, Ascot, UK)[13]. The contiguous thoracoabdominal approach was also used in some patients.

Statistical analysis

Survival was estimated using the method of Kaplan and Meier[14]. The difference between groups was assessed by the log rank test[15,16]. The 5-year survival rates include operative deaths.

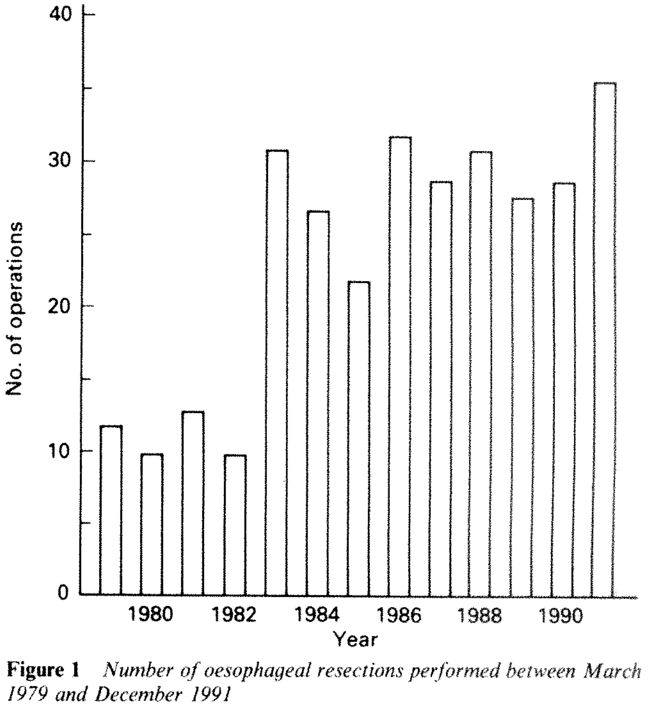

Figure 1 *Number of oesophageal resections performed between March 1979 and December 1991*

Results

A total of 216 men and 82 women aged 34–87 years underwent oesophageal resection, a male:female ratio of 2·6:1. The age distribution for all patients with oesophageal cancer obtained from the regional cancer registry was similar to that of those who had undergone oesophageal resection (*Figure 2*).

Of the 298 patients, 267 underwent a Lewis procedure, four three-stage oesophagogastrectomy and 27 thoraco-abdominal oesophagogastrectomy.

Dysphagia, weight loss and retrosternal or epigastric pain were the presenting symptoms in most patients either in combination or alone (*Table 1*). Dysphagia was the predominant symptom in 255 patients (86 per cent) and in 38 (13 per cent) was the sole complaint. Haematemesis was the presenting feature in four men and oesophageal malignancy was found in one patient during the course of investigations for chronic anaemia. In all, 52 per cent of patients tolerated symptoms for 2–4 months before the diagnosis was made. The duration of symptoms was not related to the stage of disease. For example, of 22 patients who had symptoms for 11–12 months, ten had localized tumours (N_0M_0) and only three had distant metastases, and of 50 patients with symptoms for 1–2 months, 32 had nodal involvement.

Adenocarcinoma was the predominant histological type. Histological analysis (*Table 2*) revealed that 103 tumours were squamous cell carcinoma and 180 adenocarcinoma. Most adenocarcinomas were presumed to be gastric in origin but in 21 patients (12 per cent) such tumours were found to arise in a columnar epithelium-lined (Barrett's) oesophagus. Interestingly, adenocarcinoma was the predominant tumour in men (73 per cent) while squamous cell carcinoma predominated in women (67 per cent). In addition, anaplastic carcinoma was found in 13 patients (4 per cent). One patient had a mixed lesion and another a tumour that proved impossible to define histologically.

Half the patients had evidence of metastatic spread at the time of surgery. Staging of the resected specimen in conjunction with the findings at operation revealed the numbers of patients with stage I, II, III and IV disease to be seven, 110, 142 and 39 respectively. For those with stage III disease, lymph nodes lying along the left gastric artery were the most commonly involved. Despite preoperative assessment with ultrasonography and CT, disease was frequently found to be more extensive than had been anticipated (*Table 3*). The operative mortality rate, defined as death within 30 days, was 10 per cent. Postoperative complications are given in *Table 4*.

There were eight anastomotic leaks (3 per cent); five of these patients died. Of the 298 patients, 66 (22 per cent) developed

Figure 3 *Cumulative survival curves for all patients who underwent resection (-----), those with positive nodes (·····) and those without nodal involvement (——). Operative deaths were included; there was a significant difference between the group with nodal involvement compared with that without (P < 0·05)*

anastomotic stricture requiring dilatation. The size of stapler used was 25 mm in 58 of these 66 patients; a 28-mm stapler was used for the remaining eight. The majority of anastomotic strictures occurred within 6 months of operation.

The drainage procedure was pyloroplasty in 223 patients (75 per cent) and pyloromyotomy in 50 (17 per cent). No drainage procedure was undertaken in 25 patients (8 per cent); one patient developed gastric outlet obstruction and underwent pyloroplasty 21 days after operation.

Survival

The overall actuarial 5-year survival rate of all patients is shown in *Figure 3*. Survival rates at 1, 2, 3, 4 and 5 years were 54, 39, 29, 25 and 23 per cent.

The 5-year survival rate for patients without lymph node involvement was 39 per cent while the corresponding figure was 17 per cent for the node-positive group. This difference in survival was significant ($P < 0{\cdot}05$). The actuarial 5-year survival rate for patients with stage IV disease was 15 per cent.

Discussion

A threefold increase was recorded in the number of oesophageal resections performed in this unit in 1983 compared with previous years. The reason for this is not clear but it may reflect a change in referral pattern. The main source of referrals was initially from other departments within the hospital but, as the unit became established, general practitioners referred patients directly.

The age distribution of the overall incidence of oesophageal carcinoma matches reasonably well that of the present patients who had undergone resection (*Figure 2*). This finding suggests that there was little selection of patients on the grounds of age. Patients of all ages were operated on as the biological age was considered more important than chronological age. The authors rarely used non-resectional techniques such as intubation for the palliation of malignant dysphagia.

The type of procedure used in the present series is generally considered 'palliative' even though the resection may be radical in extent. *En bloc* procedures were not used. The main aim of therapy was to restore swallowing.

Matthews *et al.*[17] compared the results of oesophageal resection undertaken by 127 surgeons who operated occasionally (averaging three or fewer resections per annum) with those of four surgeons who operated more frequently (averaging six or more resections annually). The operative and 5-year mortality rates were significantly lower in the second group. The low mortality and morbidity rates in the present series support the view that oesophagogastrectomy should be carried out by surgeons who perform this procedure frequently.

The duration of symptoms before oesophagectomy bore no relationship to the stage of disease at operation, in agreement with previous reports[18,19]. The findings indicate that spread of disease may occur without overt symptoms of dysphagia, weight loss, retrosternal pain or difficulty swallowing.

In 1990, Muller *et al.*[20] reviewed 1201 papers on oesophageal carcinoma published between 1980 and 1988; they found a mean 5-year survival rate of 20 per cent. In series containing both squamous carcinoma and adenocarcinoma, the mean 5-year survival rate was lower than in those that included only squamous cell carcinoma (18 *versus* 24 per cent). The 5-year survival rate of 23 per cent in the present series thus compares favourably with those published.

Barrett's oesophagus (columnar-lined oesophagus) has been recognized as a premalignant condition. Haggitt *et al.*[21] reported that 12 of 14 patients with oesophageal adenocarcinoma had associated Barrett's oesophagus. More recently, Hamilton *et al.*[22] found that 64 per cent of oesophagogastrectomy specimens with adenocarcinoma were from patients with Barrett's oesophagus. They emphasized that there is under-reporting of carcinoma associated with Barrett's oesophagus;

only 38 per cent of patients in their series were recognized on preoperative endoscopy and biopsy to have this association. The prevalence of Barrett's oesophagus was 12 per cent in the present series. The resection specimens were, however, not subjected to extensive histopathological examination and the prevalence of adenocarcinoma arising in Barrett's oesophagus was probably under-reported.

The importance of nodal involvement in prognosis was demonstrated by the lower 5-year survival rate for patients with compared with those without nodal involvement (17 *versus* 39 per cent). Survival was adversely affected by positive regional lymph nodes ($P < 0{\cdot}05$) and distant lymphatic metastases ($P < 0{\cdot}05$).

Postlethwait and Durham[23] reported an anastomotic leakage rate of 36 per cent in a series of 512 operations. The use of staplers for oesophageal anastomosis had made this step of the procedure much safer, leakage rates of 0–3·5 per cent being reported[12,23–25]. In the present series there was a 3 per cent incidence of anastomotic leakage, but the seriousness of this complication is shown by the fact that five of the eight patients in whom the anastomosis leaked died. Anastomotic leakage was more common after extensive gastric resection; this may have been a result of the shorter gastric tube, leading to tension at the anastomosis[26]. One patient in the present series underwent choledochoduodenostomy for common bile duct stones at the time of oesophageal resection; this may have contributed to leakage by creating tension at the anastomosis. The authors now advocate that bile duct stones be dealt with endoscopically either before or after oesophagectomy. It is important that the duodenum is thoroughly mobilized. The range of methods described to protect the oesophagogastric anastomosis indicates that there is no guaranteed way of guarding against dehiscence of an intrathoracic anastomosis. Polyglactin 910 mesh graft, lung tissue, visceral pleural patch, omentum, peritoneum, pericardium, oesophageal muscular cuffs, intercostal pedicle and gastric fundus patch have all been used for the protection of the oesophagogastrostomy[27–29]. Reinforcing sutures were used in the present series to 'inkwell' the stapled anastomosis. The initial management of anastomotic leakage was total parenteral nutrition, complete fasting, intrathoracic drainage and antibiotics, but nevertheless five of the eight patients died.

Anastomotic stricture developed in 22 per cent of patients in this series. While this is a high rate, it is comparable to that in other series using the EEA stapler[30]. The use of a small stapler (25 mm) and of reinforcing sutures to 'inkwell' the stapled anastomosis may be contributory factors. The choice of stapler was made after 'sizing' the diameter of the transected oesophagus with metal rods. In each case the largest possible stapler was used but this was, of course, dependent on the luminal width of the oesophagus. Injudicious forcing of the detached stapler head into the lumen of the transected oesophagus may result in splitting of the oesophageal wall and is to be discouraged. There may be a trade-off between the risk of anastomotic stricture using reinforcing sutures and the risk of anastomotic leakage. Dilatation of a stricture was felt preferable to the dire consequences of anastomotic leakage. Most of the anastomotic strictures presented within 6 months of operation. Only patients who complained of dysphagia were investigated.

Pyloroplasty was the drainage procedure most commonly performed, although pyloromyotomy was used in 17 per cent of patients. After pyloromyotomy, any inadvertent breach of the mucosal surface was tested with insufflation of air via a nasogastric tube. Not infrequently, however, the oesophageal tumour prevented passage of the nasogastric tube. Pyloroplasty was then performed in preference to pyloromyotomy. Dark *et al.*[31] reported that pyloroplasty was not used in a series of 449 resections. Six patients developed inadequate gastric emptying, requiring pyloroplasty. Mannell *et al.*[32] evaluated the role of pyloroplasty in the retrosternal stomach in a randomized controlled trial and found that nine of 20 patients in whom the pylorus was left intact had gastric tube stasis. The present authors now routinely perform pyloroplasty or pyloromyotomy and have not observed gastric stasis.

The 30-day mortality rate after resection was 10 per cent in the present series. This rate is similar to those in other series, especially bearing in mind the elderly population (77 per cent of patients were over 60 years old).

Intubation has been used as the primary method of treatment in many 'medical' centres in the UK. The almost unselected nature of the present series, coupled with the favourable results of resection, argue against such a policy. Intubation was rarely used. Oesophageal resection provides good results in the palliation of malignant dysphagia and is the treatment of choice in patients fit to undergo surgery. As in other series[33], adenocarcinoma was found in 60 per cent of patients. It is generally accepted that surgery is the best treatment, although radiotherapy has been advocated as an alternative for squamous cell carcinoma. However, the available evidence[34–36] indicates poor survival rates of between 5 and 10 per cent using this treatment. It is our contention that resection remains the preferred mode of treatment for carcinoma of the oesophagus of all histological types and that resection can be accomplished with acceptable morbidity and mortality rates. Furthermore, there is a reasonable long-term outlook for those with favourable stages of the disease.

Non-operative treatment of small bowel obstruction following appendicectomy or operation on the ovary or tube

This study examined the hypothesis that small bowel obstruction in patients whose only previous laparotomy was for appendicectomy or operation on the ovary or tube is unlikely to resolve with non-operative management. Results of 330 admissions for small bowel obstruction were examined. In 40 cases the only previous laparotomy was at appendicectomy or tubo-ovarian operation; in 38 (95 per cent) of these division of adhesions was undertaken compared with 154 (53 per cent) of the remaining 290 ($P < 0\cdot00001$). In the former group band adhesions were commoner (86 versus *45 per cent, $P < 0\cdot00001$), bowel resection was required more frequently (22* versus *10 per cent, $P = 0\cdot02$) and it was considered safe to give a trial of non-operative management less often (60* versus *85 per cent, $P = 0\cdot0004$). A trial of conservative management may be unsafe or not worth while in patients with obstruction following earlier appendicectomy or operation on the ovary or tube.*

In 1933 successful treatment of small bowel obstruction was reported in which some patients received nasoenteric suction and intravenous fluid therapy[1]. It was concluded:

> 'Only after this method of treating acute mechanical obstruction has been tried in the hands of many practitioners under varying circumstances will its limitations and possibilities become well defined.'

Numerous attempts have been made to predict which patients can be treated successfully with non-operative management. Continuous abdominal pain, localized pain, peritonism, tachycardia, high temperature, leucocytosis, high levels of amylase and lactic dehydrogenase, and clinical judgement have been analysed alone and in combination, in retrospective and prospective trials[2–12]. Their predictive power has been found to be disappointingly low.

Of patients presenting with small bowel obstruction caused by adhesions, 27–83 per cent are given a trial of non-operative treatment[10–14]. Between 22 and 52 per cent of these will eventually undergo laparotomy and 5–14 per cent require bowel resection for ischaemia[10–13]. When resection is needed the mortality rate can be 15–20 per cent[10,11,13].

It has been the authors' observation that, of patients presenting with small bowel obstruction, it is most uncommon for obstruction in those whose only previous laparotomy was for appendicectomy or operation on the ovary or tube to settle with non-operative management. When laparotomy is undertaken in such patients, a closed loop of bowel is typically found to be caught by a band adhesion. This type of obstruction is highly unlikely to settle without operative intervention and prolonged observation may lead to bowel ischaemia. This study was undertaken to evaluate the validity of this observation.

Patients and methods

A computerized coding system in use since 1986 identified patients with small bowel obstruction in the 6-year period 1986–1991. Patients who developed small bowel obstruction in hospital after a laparotomy and those with an obstructed external hernia were excluded. Patients with small bowel obstruction from specific causes were excluded (carcinoma in 18, radiation enteritis in nine, intra-abdominal abscess in six, Crohn's disease in three, anastomotic narrowing in one). Three sets of admission notes were studied (from the emergency department resident, the surgical registrar and the team intern), ensuring that collection of data was as reliable as possible. In five patients the nature of the previous laparotomy was unclear after reviewing the admission, original hospital and local doctor's notes, and operative findings. These were recorded as 'laparotomy (other)'.

Statistical analysis was by Fisher's exact test and two-tailed P values are given.

Results

There were 330 admissions: 127 of male patients and 203 female. The mean age was 59 (range 16–96) years. There were 260 patients in the study as 44 were admitted more than once.

In 34 cases the previous major laparotomy was for appendicectomy, through a grid-iron incision in all. In 31 this was the only procedure whereas in three cases operations on the ovary or tube had been performed. In 32 of the 34 cases division of adhesions was required while in only two was non-operative management successful. In the remaining 296 cases in the study, division of adhesions was necessary in 160 and obstruction settled with conservative management in 136. The difference between the two groups was highly significant ($P < 0\cdot00001$).

In six patients the only previous operation was on the ovary or tube: tubal ligation in three, salpingectomy in one, ovarian cystectomy in one and removal of an ectopic pregnancy followed later by a tubal ligation in one. In all six cases division of adhesions was required compared with 186 in the other 324 cases ($P = 0\cdot04$). The three patients in the appendicectomy group who had also undergone tubo-ovarian operations all required division of adhesions.

Data for the 40 cases of obstruction following appendicectomy and/or tubo-ovarian operation are summarized in *Table 1*. In this group band adhesions were the cause of obstruction in 32 of the 37 cases in which the type of adhesion was noted in the operative report, compared with 62 of 139 such cases in the remainder of the study ($P < 0\cdot00001$). Bowel

Table 1 *Outcome according to previous operation*

Previous operation	Division of adhesions	Successful conservative treatment
Appendicectomy and/or tubo-ovarian operation	38	2
Other	154	136

$P < 0\cdot00001$ (Fisher's exact test)

Table 2 *Outcome according to number of previous laparotomies*

No. of previous laparotomies	No. of cases	Division of adhesions
0	9	9 (100)
1	128	90 (70)
2	92	47 (51)
3	41	22 (54)
4	34	17 (50)
≥5	26	7 (27)
Total	330	192 (58)

Values in parentheses are percentages

Table 3 *Outcome according to previous operation in patients who had undergone only one laparotomy*

Previous laparotomy	No. of cases	Division of adhesions
Appendicectomy	31	29 (94)
Tubo-ovarian operation	5	5 (100)
Large bowel operation	32	12 (38)
Hysterectomy	17	12 (71)
Gastric operation	9	5 (56)
Other	34	27 (79)
Total	128	90 (70)

Values in parentheses are percentages. Groups other than tubo-ovarian with fewer than nine cases are included in 'Other'

resection for ischaemia was required in nine of the combined group compared with 28 of the other 290 cases ($P = 0{\cdot}02$). Seven of the nine bowel resections in the former group were in patients initially receiving non-operative treatment. It was considered safe to undertake a trial of non-operative management in 24 of the 40 combined cases, compared with 247 of the remaining 290 ($P = 0{\cdot}0004$).

In *Table 2* outcome is presented according to the number of previous laparotomies. In nine cases patients had not undergone a previous laparotomy; in five a trial of non-operative management was undertaken. In all nine cases division of adhesions proved necessary, compared with 183 of the remaining 321 cases ($P = 0{\cdot}01$). This group followed a similar pattern to patients who had had an appendicectomy and/or tubo-ovarian operation, as all nine had band adhesions and three required bowel resection for ischaemia. In *Table 3* the outcome of those who had undergone only one previous laparotomy is summarized.

In the 330 admissions, bowel resection for ischaemia was required in 37, in which 28 patients were initially managed non-operatively, with a mean delay from presentation to laparotomy of 34 (range 4–96) h. There were 13 deaths, 12 of which occurred in patients initially given non-operative treatment. Four did not have a laparotomy before death; of the nine who did, five required bowel resection, one of whom had had only an appendicectomy. The overall mortality rate was 4 per cent, rising to 14 per cent in those who required bowel resection.

Discussion

Of patients presenting with small bowel obstruction, it is unlikely for obstruction in those whose only previous laparotomy was for appendicectomy or tubo-ovarian operation to settle with non-operative management. This group was distinctive in other ways: band adhesions were found more frequently and bowel resection for ischaemia required more often. It was considered safe to give a trial of non-operative management less often. This group probably lies at one end of a spectrum and the outcome of episodes of adhesional small bowel obstruction is determined, in part, by the number and type of previous laparotomies. Band adhesions appear to be a major influence on outcome.

The finding that patients who had undergone appendicectomy and/or tubo-ovarian operation had a trial of non-operative management less often than others may reflect sound clinical judgement. There is a tendency, however, to offer non-operative treatment to patients who have had multiple previous laparotomies. Surgeons may be concerned that very dense adhesions will result in a prolonged and hazardous operation. Ellis[15] has suggested that patients who have undergone multiple difficult laparotomies for lysis of adhesions may have intestinal loops so matted that they are unlikely to become strangulated. This tendency may be responsible for some of the difference in the laparotomy rate between those who have had one previous laparotomy and those who have had multiple procedures. The present study has identified a group of patients, who could be identified on admission, who eventually underwent division of adhesions in 95 per cent of cases.

These findings may be relevant only to similar populations with similar standards of healthcare. The state of the appendix at appendicectomy may be a determinant of band adhesion formation and patients with bowel obstruction may initially be managed in smaller hospitals and referred only if they require operative management.

Immediate laparoscopic division of adhesions may be a particularly suitable form of management in this group of patients and may reduce the number of bowel resections required. Adhesion formation might be reduced by the application of recombinant tissue plasminogen activator[16]. One early report suggests that laparoscopic appendicectomy is associated with less adhesion formation[17].

The proportion of peripheral blood mononuclear cells expressing the T helper cell phenotype and levels of antiendotoxin core antibody, interleukin (IL) 6 and C-reactive protein (CRP) were determined within 48 h of admission in a group of 29 patients with acute pancreatitis (16 mild, 13 severe attacks). There was a significant decrease in the proportion of T helper cells (12·2 versus *34·9 per cent,* $P < 0{\cdot}01$*) and significant increases in levels of IL-6 (69·5* versus *< 10 pg/ml,* $P < 0{\cdot}01$*) and CRP (119* versus *30·5 mg/l,* $P < 0{\cdot}01$*) in severe compared with mild attacks. During the convalescent stage at 3 months after admission, severe attacks were characterized by a significant increase in the proportion of T helper cells compared with the acute period (22·4* versus *10·6 per cent,* $P < 0{\cdot}01$*). A persistently low proportion of T helper cells was associated with residual pancreatic necrosis. The presence of circulating endotoxin was demonstrated in two mild and two severe attacks using the* Limulus *amoebocyte lysate assay, and abnormal levels of antiendotoxin core antibodies were found in 70 and 92 per cent of mild and severe attacks respectively. There was a strong inverse correlation between levels of CRP and the proportion of T helper cells in severe disease (*$r = -0{\cdot}76$*,* $P = 0{\cdot}004$*). Translocation of endotoxin from the gastrointestinal tract may partly explain the abnormal levels of T helper cells, IL-6 and CRP.*

After a severe attack of acute pancreatitis sepsis is now the leading cause of death[1]. Abnormalities in immune function such as a decreased proportion of T helper lymphocytes in the population of peripheral blood mononuclear cells[2], lowered production[3,4] of interleukin (IL) 2, decreased T cell proliferation[2] and increased prostaglandin E_2 production by monocytes[5] occur in patients with burns and trauma and correlate with the incidence of sepsis and outcome. A decrease in delayed-type skin hypersensitivity is common to patients with burn injury, blunt trauma[6] and acute pancreatitis[7], but the extent of other abnormalities of immune function in pancreatitis remains unclear.

Suppression of cellular immune function may result in part from exposure to bacterial endotoxin, a constituent of the Gram-negative bacterial outer membrane that comprises a lipid A–oligosaccharide core and a polysaccharide side chain. In addition to its role in the 'sepsis syndrome'[8], exposure to endotoxin may reduce the proportion of T helper cells in peripheral blood[9]. Endotoxin probably exerts many of its actions via cytokines that are released from monocytes[10–12]; these include IL-6, which is involved in B and T cell maturation, and is a reliable indicator of sepsis[13].

Previous studies have demonstrated that endotoxaemia is common in severe acute pancreatitis[14,15]. Reduced levels of CD4-positive cells (T helper lymphocytes) may be found in such patients in addition to other markers of recent endotoxin exposure, and these abnormalities may provide a potential target for immunomodulatory therapy. To overcome the difficulties associated with detection of endotoxin by the *Limulus* amoebocyte lysate test[16], assays for the measurement of circulating endogenous antiendotoxin core antibodies have been developed[17,18]. In the present study, levels of endotoxin, antiendotoxin core antibody, IL-6, C-reactive protein (CRP) and circulating T helper cells were measured in 29 patients with acute pancreatitis.

Patients and methods

Patients

Criteria for the diagnosis of acute pancreatitis were acute abdominal pain associated with a plasma amylase level >1000 units/l and a consistent clinical course. Attacks were classified as mild or severe; a severe attack was defined as a fatal outcome or the development of pancreatic necrosis, abscess or pseudocyst. Patients were cared for in a number of different hospitals but all were reviewed regularly by one author (P.J.C.) until discharge from hospital.

One patient underwent surgical pancreatic debridement and the remainder were treated conservatively with intravenous fluids, parenteral nutrition and antibiotics as indicated clinically. Venous blood was collected within 48 h of admission.

Normal proportions of T helper cells in peripheral blood mononuclear cell preparations were determined for 11 healthy controls. T helper cell proportions were also determined in eight patients with mild and six with severe pancreatitis 3 months after the acute attack.

Methods

Venous blood samples were collected within 48 h into preservative-free heparinized tubes for T cell studies (heparinized using 25 units/ml Monoparin; CP Pharmaceuticals, Wrexham, UK) and into endotoxin-free glass tubes for serum studies. Samples for endotoxin assays were allowed to clot and then centrifuged; the serum was harvested and frozen at −20°C until analysis.

Presented to the Pancreatic Society of Great Britain and Ireland in London, UK, November 1991 and published in abstract form as Gut *1992;* **32**: *56*

T lymphocyte studies. Density-gradient separation was performed by centrifugation for 30 min at 400g over Lymphoprep (Nycomed, Oslo, Norway). A volume of 100 μl cell suspension (1×10^6 cells/ml) was added to wells on a V bottom microtitre plate. The plate was centrifuged at 800g for 5 min at 4°C, the supernatant discarded, and the cells resuspended. An aliquot of 100 μl mouse antihuman antibody directed at the CD4 epitope (OKT4 antibody) was added to each well and incubated at 4°C for 45 min in the dark. (An antibody to a melanoma cell line, α-mel, was used as a negative control.) The cells were washed three times in phosphate-buffered saline (PBS) containing 2 per cent fetal calf serum (FCS), 2 per cent normal human serum and 10 mmol/l sodium azide. A volume of 50 μl goat antimouse immunoglobulin (Ig) G conjugated with fluorescein (Sigma Chemicals, Poole, UK) and diluted 1:150 with PBS–FCS–normal human serum–azide was added and reincubated for a further 45 min in the dark at 4°C. After three further washes the cells were fixed with PBS–FCS–normal human serum–azide containing 2 per cent formalin.

Flow cytometric analysis was performed using an EPICS V flow cytometer (Coulter Electronics, Luton, UK). Forward *versus* 90° light scatter was measured and results expressed as the percentage of CD4-positive cells in a sample of 10 000 peripheral blood mononuclear cells counted.

Endotoxin assay. Levels of endotoxin were determined using a kinetic chromogenic *Limulus* amoebocyte lysate method based on the endotoxin-specific Endospecy assay[19] (Seikagaku, Tokyo, Japan). Briefly, freshly thawed test sera were diluted 1:10 in pyrogen-free water and heated to 85°C for 15 min. Endotoxin standard (*Escherichia coli* O111 lipopolysaccharide S (1 ng, 12 endotoxin units); Kabi Diagnostica, Milton Keynes, UK) was diluted in endotoxin-free normal human serum (the negative control). Endospecy reagent was simultaneously added to test samples, standards and controls using a transfer plate. The plate was read at 405 nm (reference wavelength 650 nm) on a Maxline plate reader (Alpha Laboratories, Eastleigh, UK) at 37°C. Values >5 pg/ml are not found in sera from healthy individuals using this method (G.R.B., unpublished data).

Ig G and Ig M antiendotoxin core antibody levels were measured as described previously[17,18]. The normal ranges for Ig G and Ig M antiendotoxin core antibody were determined using blood from 1000 healthy donors and data expressed as a percentage of the control median (defined as 100 per cent).

Interleukin 6 assay. Serum IL-6 levels were determined using a commercial enzyme-linked immunosorbent assay (ELISA) kit (Quantikine; British Biotechnology, Slough, UK) and read at 450 nm on an ELISA plate reader (Titertek Multiscan MCC; Flow Labs, Rickmansworth, UK). This assay has a working range of 10–2000 pg/ml and an interassay coefficient of variation <10 per cent.

C-reactive protein assay. CRP was measured using an ELISA. Briefly, serum samples were diluted and incubated on microwell plates coated with an antibody fragment for antigen binding ($F(ab)_2$) prepared from a commercially available rabbit anti-CRP antibody (Dako, High Wycombe, UK). After 2 h the plate was washed and horseradish peroxidase-conjugated rabbit anti-CRP antibody (Dako) added for 1 h. After washing, the chromogen *o*-phenylenediamine in citric acid–phosphate buffer containing hydrogen peroxide was added to each well, incubated for 15 min and the reaction stopped by addition of 1 mol/l sulphuric acid. Dako CRP calibrant and serum samples were read on a Titertek Multiscan MCC plate reader at 450 nm. The sensitivity of this assay was 0·1 μg/ml with an interassay coefficient of variation of 2–15 per cent using plasma samples with CRP concentrations ranging from <1 to 400 mg/l.

All samples were run in triplicate. Data are expressed as median (interquartile range) and statistical analysis performed using the Mann–Whitney U test and paired t test as appropriate. Correlation coefficients were calculated by linear regression.

Results

Twenty-nine patients were studied: 16 suffered mild and 13 severe attacks of acute pancreatitis. The two groups were similar with respect to age and aetiology (*Table 1*). Computed tomography showed that the nine patients who survived after severe attacks had pancreatic necrosis. T cell studies were performed on all patients with severe disease and on ten with mild attacks. Serum studies were performed on all patients with mild disease and on 12 with severe attacks.

CD4 expression

Between 30 and 40 per cent of mononuclear cells expressed CD4 surface antigen in the control population. The median expression of CD4-positive mononuclear cells was 34·9 and 12·2 per cent for patients suffering mild and severe attacks respectively (*Figure 1*). A significant increase in the proportion of mononuclear cells expressing CD4 antigen was observed during convalescence in patients who had survived severe attacks (22·4 *versus* 10·6 per cent in the acute period, $P < 0.01$) (*Figure 2*).

Endotoxaemia and circulating antiendotoxin core antibodies

Circulating endotoxin was detected in only four patients (two with mild, two with severe pancreatitis) but abnormalities in levels of endogenous antibodies to the endotoxin core were common. There was a tendency for patients with severe attacks to have increased levels of Ig G antibody compared with those with mild disease (median 190 *versus* 108 per cent). This difference was not, however, statistically significant. In contrast, a significantly reduced level of Ig M antiendotoxin core antibody was found in patients suffering either severe or mild compared with healthy controls (*Figure 3*).

Interleukin 6

Serum levels of IL-6 were raised in seven of 12 patients with severe attacks but in none of those with mild disease. The serum level of IL-6 in patients with mild attacks was <10 pg/ml in

all but one (11 pg/ml), compared with a median of 69·5 pg/ml for patients suffering severe attacks ($P < 0·01$). IL-6 was not detected in control sera.

C-reactive protein

Raised serum levels of CRP (>10 mg/l) were found in 23 patients (*Figure 4*). There was a strong negative correlation between the percentage of CD4-positive cells and the level of CRP in patients with severe attacks ($r = -0·76$, $P = 0·004$).

Discussion

CD4-positive T helper lymphocytes are the primary source of IL-2, which is responsible in part for a variety of cellular immune responses[20–25]. The percentage of CD4-positive cells is decreased in patients with acquired immune deficiency syndrome, following thermal injury and blunt trauma[3], and after infusion of endotoxin[9]. Depressed delayed-type skin hypersensitivity reflects altered cellular immune function and correlates with septic morbidity and mortality in those with burns, trauma and acute pancreatitis[7]. Conversion from anergy to reactivity is a good prognostic sign after surgery or major trauma. Administration of recombinant IL-2 in models of burn injury returns some lymphocyte abnormalities[3,26] to normal and improves survival. The reduction in number of CD4-positive cells, and consequently lower IL-2 levels, may be partly responsible for the depressed cellular immunity seen in patients with severe acute pancreatitis.

In the present study, the decreased levels of T helper cells observed in patients with severe attacks returned towards normal in the convalescent phase, suggesting a reversible mechanism. The level of CD4-positive cells may have prognostic value in a given attack but, more importantly, suggests that immunomodulation has therapeutic potential in severe acute pancreatitis. The strong correlation between high levels of CRP and low percentage of CD4-positive cells suggests that the CD4 level is also a marker for necrosis[27].

Changes in the T cell profile may be caused by exposure to endotoxin but circulating endotoxin was demonstrated in only four patients. This may reflect the short half-life of the endotoxin molecule and the transient nature of endotoxaemia as measured by the *Limulus* assay. In contrast, changes in antibody levels persist for many days and are a better indicator of exposure to endotoxin. Endogenous antibody levels to the core determinant of endotoxin were therefore determined. An early reduction in circulating IgG antibodies to the endotoxin core may be followed by a rebound increase in IgG antibody levels[28]. Similar changes in IgM antibody levels to the endotoxin core occur, but in this case the rebound occurs earlier and is transient (G.R.B., unpublished data). In the present study, abnormal levels of IgG or IgM antiendotoxin core antibodies were found in 70 per cent of mild attacks and 92 per cent of severe attacks but an increase in serum IL-6 level was seen in severe attacks only. This may reflect a differential response to endotoxin in severe disease or may result from the occurrence of repeated episodes of endotoxaemia that were not identified.

If endotoxin is an important factor in acute pancreatitis then it probably exerts its actions via the cytokines released by monocytes. Classically, tumour necrosis factor (TNF) release has been associated with the detrimental effects of endotoxin exposure. Raised TNF levels in severe acute pancreatitis have been demonstrated[29,30]. TNF is a positive regulator[31] of IL-6, which may explain these findings. In turn, IL-6 synergizes with IL-1, promotes B cell differentiation and antibody production, promotes the acute-phase response and circulates complexed to α_2-macroglobulin[32].

This study describes immunological abnormalities in patients with acute pancreatitis and, perhaps more importantly, demonstrates immunological changes similar to those found after thermal, surgical or traumatic injury. The similarity between these conditions offers fresh hope for the management of patients with necrotizing pancreatitis. Administration of IL-2[26], cyclo-oxygenase inhibitors[33,34], and monoclonal antibodies directed against endotoxin[35] or its related cytokines[12] may prove useful in the treatment of patients with severe acute pancreatitis associated with compromised cellular immune function, high rates of septic complication and death.

Pancreatic fistula cured by an endoprosthesis in the pancreatic duct

J. Kiil and H. Rønning

Department of Surgery, Randers Centralsygehus, DK-8900 Randers, Denmark
Correspondence to: Dr J. Kiil

Pancreatic fistula can develop in patients with chronic pancreatitis or trauma[1–3]. Symptoms from the pancreas are often absent or mild, and diagnosis usually relies on the demonstration of complications from other organs, particularly the lungs. Major pleural effusion, usually on the left side, with a high concentration of pancreatic amylase and pulmonary symptoms may be the first sign of pancreatopleural fistula. Fluid collection in the abdomen may also indicate a fistula. Endoscopic retrograde cholangiopancreatography (ERCP) is essential for the diagnosis.

Two patients with pancreatic fistula are presented, both of whom were cured by insertion of an endoprosthesis into the main pancreatic duct. Both patients had a long history of alcohol abuse.

Case reports

Patient 1

A 65-year-old man was admitted in a poor general condition. Chest radiography showed a large left pleural effusion that had not been present 1 year earlier. The fluid contained amylase at high concentration (> 20 000 units/l). The insertion of an external 10-Fr pigtail catheter into the pleural cavity was followed by the daily drainage of 800 ml fluid. ERCP (*Figure 1a*) showed a slightly abnormal main pancreatic duct, compatible with chronic pancreatitis, with a fistula arising just to the left of the spine and communicating with the left pleural cavity. A guidewire (Tracer wire guide; William Cook Europe, Bjaeverskov, Denmark) was passed through the main pancreatic duct until the tip lay 1 cm to the left of the origin of the fistula; a 5-Fr straight endoprosthesis with multiple side holes was inserted along the guidewire. Oral food intake was not restricted and the patient received no additional medication or parenteral nutrition. Secretion of fluid through the pleural stent stopped immediately after ERCP; the patient's condition improved rapidly, allowing him to leave hospital 16 days later. ERCP performed at 3 months showed no leak in the pancreatic duct (*Figure 1b*) and chest radiography was normal. Endoscopic pancreatic sphincterotomy was performed to ensure unobstructed flow and the endoprosthesis was removed. The patient remains well 10 months later.

Patient 2

A 66-year-old woman underwent abdominal ultrasonography because of a 1-year history of weight loss and abdominal discomfort. ERCP (*Figure 2a*) showed a large fistula from the main pancreatic duct extending subhepatically as far as the diaphragm. A 5-Fr endoprosthesis was placed in the pancreatic duct with the proximal end at the fistula opening, and sphincterotomy was performed using a needle papillotome along the endoprosthesis. After 2 uneventful months, during which time all abdominal symptoms subsided and the patient gained 2 kg in weight, repeat ERCP was performed. The fistula was still present but had narrowed considerably (*Figure 2b*). The common bile duct (CBD) was compressed in its intrapancreatic course, compatible with chronic pancreatitis. A second endoprosthesis was inserted to accelerate healing of the fistula. Some 2 months later ERCP (*Figure 2c*) showed complete healing with filling of the pancreatic duct beyond the level of the fistula for the first time. Compression of the CBD was unaltered but was causing no symptoms. Both endoprostheses were removed without recurrence of symptoms.

Discussion

Two kinds of treatment have been recommended for pancreatic fistula. Somatostatin therapy plus parenteral nutrition can reduce fistula output in patients with a pancreatopleural lesion and lead to subsequent closure of the fistula in a number of patients[4,5], but it is time-consuming and expensive. Resection of the part of the pancreas to the left of the fistula is an effective but major undertaking[1,2].

In the present patients it seemed likely that secretion through the fistula would stop if the natural flow through the duct system were facilitated by relief of any blockage. Insertion of an endoprosthesis eliminated any potential obstruction by minor duct strictures or the papillary sphincter and led to prompt cessation of secretion from the fistula track with healing of the lesion within a few months. Insertion of the endoprosthesis was relatively easy once the guidewire had been passed. Tortuous and stenotic ducts can be difficult or impossible to negotiate[1], but the new Tracer wire guide greatly facilitates this manoeuvre.

This endoscopic management of pancreatic fistula is inexpensive and convenient, being similar to the method

advocated for treatment of biliary tract fistula[6]. As neither of the patients described had duct obstruction, except perhaps at the papilla, the rationale for performing sphincterotomy at the time of stent removal was to prevent subsequent recurrence of the fistula. The manoeuvre has proved successful in the short term.

The effect of early nifedipine therapy on acute renal allograft rejection was studied in 170 adult cadaveric transplant recipients. Acute rejection occurring in the first 3 months after transplantation was diagnosed by Tru-cut biopsy and the severity of each rejection episode assessed histologically. The incidence of acute rejection was significantly lower in patients treated with nifedipine (29 of 80; 36 per cent) than in controls (52 of 90; 58 per cent) (P < 0·01) and there was a higher proportion of histologically mild rejection episodes in the former group (P < 0·01). Multivariate analysis confirmed that nifedipine exerted a significant independent effect on the incidence of early acute rejection. Other factors identified in the multivariate model as influencing rejection were human leucocyte antigen (HLA) matching at the DR locus, blood level of cyclosporin during the first week, HLA matching at the B locus, donor age and donor sex. The 1-year graft survival rate was 88·6 per cent in patients given nifedipine and 63·8 per cent in controls (P < 0·02). These data suggest that nifedipine therapy has a useful role in human renal transplantation.

The calcium channel blocker nifedipine relaxes vascular smooth muscle and is therefore used extensively as an antihypertensive agent. Cyclosporin therapy is often complicated by sodium-dependent hypertension and nifedipine has commonly been used in renal transplant recipients to treat this condition. Nifedipine also ameliorates cyclosporin nephrotoxicity[1] and reduces the incidence of delayed graft function after renal transplantation[2].

Recent experimental evidence suggests that nifedipine depresses a variety of functions in both the afferent and efferent limbs of the immune response[3]. The aim of the present study was to determine whether early nifedipine therapy has an effect on acute graft rejection after adult cadaveric renal transplantation. The study was limited to the first 12 weeks after transplantation as this is known to be the period in which rejection is most common.

Patients and methods

The outcome of a consecutive series of 187 cadaveric renal transplants performed between January 1986 and January 1991 was analysed retrospectively. Eleven patients who suffered non-immunological graft failure in the first week after transplantation and six who received calcium channel-blocker therapy with drugs other than nifedipine were excluded from further analysis. The 11 non-immunological failures were all caused by early thrombosis; histological analysis excluded rejection. Only four of these 11 patients were being treated with nifedipine. The remaining 170 cadaveric renal transplant recipients formed the study group.

Data recorded prospectively were retrieved from computerized unit records and UK Transplant Service files. Hospital notes and drug charts were examined retrospectively to identify the use of calcium channel blockers in the preoperative period and in the 12 weeks after transplantation. Nifedipine was prescribed for hypertension according to clinical need. The dose used (10–40 mg twice daily) was determined by the severity of hypertension. The influence of the following variables on rejection rates was studied: recipient age and sex; cause of renal failure; hypertensive status; current type of dialysis; number of previous transplants; donor age, sex and blood group; first warm ischaemia time; second warm ischaemia time (anastomosis time); cold ischaemia time; presence of panel-reactive lymphocytotoxic antibodies in current and historical recipient sera; human leucocyte antigen (HLA) mismatch between recipient and donor at the A, B and DR loci (scored 0–6); and type of immunosuppression used.

Immunosuppression protocol

In the first year of the study, patients received conventional immunosuppressive therapy using azathioprine (2–3 mg per kg per day) and low-dose steroids (starting at 20 mg/day gradually decreasing to 10 mg/day by 6 months after transplantation). Cyclosporin therapy was used in all other patients at a dose of 10–15 mg per kg per day either in combination with low-dose steroids or as part of triple therapy with steroids and azathioprine.

Whole-blood cyclosporin levels were measured using a radioimmunoassay kit with doses being adjusted to maintain trough levels in the range 400–800 ng/ml.

Acute rejection episodes occurring during the 12 weeks after transplantation (early acute rejection) were recorded. Acute graft rejection was defined using a combination of clinical findings (graft tenderness or swelling; pyrexia; diminishing urine output; response to steroid pulsing), biochemical data (serum creatinine and whole-blood cyclosporin levels) and the results of allograft histology (Tru-cut needle biopsy; Travenol Laboratories, Thetford, UK). Only one patient with suspected rejection was not submitted to Tru-cut biopsy, for technical reasons. The histological severity of rejection was classified as mild, moderate or severe according to the density of the mononuclear cell infiltrate. First rejection episodes were treated by three daily pulses of 0·5 g intravenous methylprednisolone. Steroid-resistant or particularly severe rejection episodes were treated with a 10–14-day course of either the monoclonal antibody OKT3 (Cilag, High Wycombe, UK) or horse antilymphocyte globulin (Merieux, Maidenhead, UK). Patients were followed routinely in the transplant clinic and form a consecutive series apart from the exclusions stated.

Statistical analysis

Univariate statistical analysis was performed using the χ^2 test for categorical variables and Student's unpaired t test for continuous variables. Multivariate analysis involved use of the Epidemiological Graphics Estimation and Testing (EGRET) package (Research Corporation, Seattle, Washington, USA). Stepwise Cox regression analysis was performed to determine factors independently associated with the development of acute rejection. All factors except calcium channel-blocker therapy were initially eligible for inclusion; this allowed assessment of the effect of calcium channel blockers *per se*. Patients lost to follow-up within the first 12 weeks were censored at the point at which they were last seen.

The effects of individual variables on graft survival were analysed by plotting Kaplan–Meier[4] curves and the statistical significance of differences determined using the log rank test[5]. Graft loss was defined

Presented to the Association of Surgeons of Great Britain and Ireland in Jersey, UK, April 1992

0007-1323/93/101318-04 © 1993 Butterworth–Heinemann Ltd

as patient death, retransplantation or return to dialysis. Death from any cause was included in the analysis.

Results

Data from 170 renal transplants were available for analysis. These were performed in 114 men and 56 women of mean(s.d.) age 40·5(13·3) (range 16–70) years. Fifty-four patients were ≥50 years of age. Immunosuppressive treatment given was azathioprine and prednisolone in 32 patients, cyclosporin and prednisolone in 117 and triple therapy in 21.

Eighty patients received oral nifedipine therapy (10–40 mg twice daily) in the first 12 weeks after transplantation; 46 were already taking nifedipine at the time of admission for transplantation and 34 were started on therapy in the first 2 weeks after operation. Ninety patients did not receive nifedipine at any time during the 12 weeks after transplantation. The immunological and demographic characteristics of these two study groups are shown in *Table 1*. There were no statistically significant differences in the level of HLA mismatching or type of immunosuppression used. There was no difference in the mean(s.e.m.) dose of cyclosporin used during the first 12 weeks in patients receiving nifedipine compared with controls (6·02(0·27) *versus* 5·35(0·34) mg per kg per day, $P = 0{\cdot}13$) nor any difference between the mean(s.e.m.) whole-blood levels of cyclosporin (340(30) *versus* 320(28) ng/ml, $P = 0{\cdot}63$).

Incidence and severity of rejection

In the 80 patients receiving nifedipine there were 32 acute rejection episodes in 29 patients (26 had one rejection, three had two). In the control group of 90 patients there were 73 rejection episodes in 52 patients (35 had one rejection, 13 had two episodes, four had three). The proportion of patients with at least one episode of acute rejection was significantly lower for those given nifedipine (29 of 80 (36 per cent) *versus* 52 of 90 (58 per cent); $\chi^2 = 7{\cdot}87$, 1 d.f., $P < 0{\cdot}01$). A Kaplan–Meier plot showing the time to first acute rejection confirmed a significant reduction in rejection rate in patients treated with nifedipine (log rank $\chi^2 = 9{\cdot}52$, 1 d.f., $P = 0{\cdot}002$; *Figure 1*).

Analysis of the histological severity of rejection demonstrated less severe episodes in patients treated with nifedipine (*Table 2*). This was the result of a higher proportion of mild and a lower proportion of moderate rejections; there was no difference in the number of severe episodes. Six patients in each group required treatment with OKT3.

Multivariate analysis

The final model obtained in the Cox regression analysis included: HLA mismatches at the DR locus, blood level of cyclosporin in the first week, HLA-B mismatches, donor age, donor sex and nifedipine therapy (*Table 3*). Matching at the HLA-DR locus had the most powerful effect. None of the other variables examined significantly improved the fit of the model. The first-week and 3-month readings for cyclosporin dose and blood level were modelled as continuous variables. Patients receiving cyclosporin after the first week were coded as zero for the first-week reading of both cyclosporin dosage and blood level. Initially, ten patients were excluded from the analyses

since there were no 3-month readings for cyclosporin dose and blood level; these patients were lost to follow-up before this time point. Since it was found that neither cyclosporin dose nor blood level at 3 months was associated with rejection the model was refitted on the larger database including these ten patients. The final model obtained is therefore based on 153 observations. The addition of polynomial terms for donor age and cyclosporin level in the first week did not improve the fit of the model significantly.

The hazard ratios in *Table 3* are a measure of the association between each variable and rejection. The adjusted hazard ratios include the effects of all items in the model, as described above. For categorical variables a hazard ratio is given for each level of the variable apart from the first, which defines the baseline value. Each hazard ratio thus indicates how much more or less likely it is for a patient to suffer graft rejection. For example, patients not receiving nifedipine therapy are 1·62 times more likely to experience acute rejection than those given the drug. The hazard ratios for the continuous variables in *Table 3* indicate how much the risk of rejection changes for every incremental increase of the continuous variable. For example, the risk of rejection increases 1·02 times for every 1-year rise in the age of the donor. A 10-year-old donor is therefore associated with a $1·02^{10}$ (i.e. 1·22) times higher risk than a 1-year-old donor.

Renal function

Serum creatinine levels were lower in patients treated with nifedipine at 3, 6, 12 and 24 months after transplantation, but the differences were not statistically significant at the 5 per cent level.

Graft survival

Fourteen of the 80 transplants (18 per cent) in patients given nifedipine failed; there were nine graft losses resulting from rejection, four non-immunological graft losses and one death. Twenty-nine of the 90 control transplants (32 per cent) failed; there were 22 secondary to rejection, six non-immunological losses and one death. Graft survival was significantly better in patients treated with nifedipine than in controls (log rank $\chi^2 = 7·91$, 1 d.f., $P = 0·01$; *Figure 2*). The 11 early graft losses that resulted from non-immunological failure were included in the data used to produce *Figure 2*.

Discussion

The molecular events that lead to T cell activation and proliferation suggest a basis for the immunosuppressive action of nifedipine. Acute cellular rejection is mediated by T lymphocytes, the process being initiated by the presentation of foreign antigen to helper T cells in the allograft. This process leads to T lymphocyte activation, the production of cytokines such as interleukin (IL) 2, the expression of IL-2 receptors on the cell surface and proliferation into a clone of cytolytic T cells. *In vitro* studies have shown that the influx of calcium ions across the lymphocyte membrane is a critical factor in the activation of T cells by mitogens[6,7]. In addition, mitogen-stimulated lymphocyte proliferation is inhibited by a calcium-free medium and inactive lymphocytes become reactivated only when calcium is reintroduced[8].

It can therefore be hypothesized that nifedipine reduces the immune response to an allograft by limiting the transmembrane flux of calcium that is important for lymphocyte activation and proliferation. Evidence to support this theory comes from *in vitro* studies, which have demonstrated that the calcium channel blockers verapamil, nifedipine and diltiazem exhibit a dose-dependent suppression of mitogen-stimulated T cell proliferation[9–12]. Indeed, this finding has been confirmed for nicardipine and diltiazem therapy in humans[13]. Verapamil also decreases the cytolytic capability of T cells and natural killer cells[12].

The mechanism of action of the immunosuppressant effect of the calcium channel blockers can only be hypothesized, although for verapamil at least there is evidence to suggest that IL-2 production and expression of IL-2 receptors are not involved[3]. The immunosuppressant action of calcium channel blockers may involve a non-calcium channel-dependent mechanism[3].

The results of the present analysis concur with those of a small randomized study of the effects of early treatment with verapamil[14], in which significantly fewer patients given verapamil were treated for rejection than in a control group (three of 22 *versus* ten of 18). The mechanism of action may differ as verapamil is known to increase blood levels of cyclosporin, whereas nifedipine has no effect on the haemodynamics of cyclosporin[15]; this finding is confirmed in the present study.

Improved renal function has been associated with nifedipine therapy previously[16,17] and may be a direct effect of reduced graft rejection, a result of reduced cyclosporin nephrotoxicity[1] or a combination of both. The diagnosis of cyclosporin toxicity is a rather complicated process of exclusion and it is impossible to quantify the role of each factor in improving renal function. Although significantly better graft survival was demonstrated in patients treated with nifedipine it is not certain that this results from the effects of the drug *per se*. For this issue to be settled, a Cox regression analysis of the survival data would have to be performed to allow for differences in other baseline variables. That nifedipine has an immunosuppressive effect adds an exciting new dimension to the use of this drug. A large randomized trial is now required.

Cytokines are powerful modulators of immune responses, the local production of which could be relevant to the interaction between tumour and immune system. This study investigated the transcription of genes encoding interleukin (IL) 2, IL-4, IL-10 and interferon (IFN) γ in lymphocyte-infiltrated renal cell carcinoma biopsies from ten patients using the reverse polymerase chain reaction technique. Autologous peripheral blood mononuclear cells and healthy renal parenchyma tissue were tested in parallel. The β-actin gene, used as a positive control, was transcribed in all samples. In contrast, transcription of cytokine genes was confined to tumour biopsies: IL-2 gene transcripts were detectable in five biopsies and IL-10 transcripts in seven. IL-4 and IFN-γ gene transcripts were detectable in one biopsy each. In two patients no cytokine gene transcription could be identified. These data underline that heterogeneous patterns of cytokine gene transcription can be observed in renal cell carcinoma biopsies. Although transcription of an immunostimulatory lymphokine such as IL-2 was observed in 50 per cent of biopsies, the most frequently transcribed cytokine gene coded for an inhibitory factor, IL-10.

Most human neoplasms are infiltrated by lymphocytes[1]. Cultured tumour-infiltrating lymphocytes have been used in clinical trials evaluating adoptive immunotherapy in neoplastic disease[2], but the nature of the interaction between such lymphocytes and tumour cells is unclear.

Lymphocyte infiltration of tumours might result from recognition by T cells of specific antigens. A tumour-specific antigen has been identified in melanoma and its sequence determined[3], and the T cell receptor variable region usage in tumour-infiltrating lymphocytes has been shown to differ from that in autologous peripheral blood mononuclear cells[4,5]. These data suggest the possibility of antigen-driven T cell selective events. Evidence that tumour-infiltrating lymphocytes express typical surface activation markers, different from those of autologous peripheral blood mononuclear cells, has been reported[6,7]. Taken together, these findings characterize tumour-infiltrating lymphocytes as an activated cell population, possibly because of antigenic stimulation.

Under physiological conditions, lymphocyte triggering is accompanied by the production of cytokines, which play a crucial role in the generation of antitumour cytotoxic activity[8]. Production of inhibitory and stimulatory cytokines has been observed in neoplastic cells, and this may have an impact on immune responses. For example, depressed immune responsiveness in patients with glioblastoma has been related to the production of transforming growth factor β_2 by tumour cells[9]. Conversely, neoplastic cell line transfection with interleukin (IL) 2, IL-4 or interferon (IFN) γ genes[10–12] has been shown to induce vigorous and long-lasting antitumour immunity.

To obtain data reflecting *in vivo* cytokine gene transcription, without risk of the artefacts inherent in cell separation or culture, the transcription of genes coding for IL-2, IL-4, IL-10 and IFN-γ was investigated in freshly excised lymphocyte-infiltrated renal cell carcinoma biopsies. Reverse polymerase chain reaction (PCR) technology, characterized by extreme sensitivity in the detection of small amounts of messenger RNA, was employed.

Patients and methods

Ten consecutive patients (seven men, three women) undergoing surgical treatment for renal cell carcinoma were studied. The mean(s.d.) age was 66(11) (range 50–82) years. Primary tumours were studied in eight patients and bone metastases in two. Tumour biopsies and, when possible, normal tissue from the affected kidney and peripheral blood mononuclear cells were collected simultaneously at the time of surgery.

Flow cytometry

Single-cell suspensions were obtained by enzymatic treatment of surgical biopsies, as previously described[7]. Tissues were finely minced and incubated at room temperature for 2 h in RPMI 1640 (Gibco, Paisley, UK) containing 0·1 per cent (w/v) collagenase type IV, 2·4 units ml^{-1} hyaluronidase type V and 0·01 per cent (w/v) DNAse (all from Sigma Chemicals, St Louis, Missouri, USA). Cells were washed and stained with optimal dilutions of commercial fluorochrome-labelled monoclonal antibodies directed against cluster differentiation (CD)3, CD69, human leucocyte antigen (HLA) DR (Becton–Dickinson, Mountain View, California, USA) or CD45RO (Dako, Glostrup, Denmark) surface determinants. After 30 min incubation at 4°C, cells were extensively washed and analysed using a FACScan flow cytometer (Becton–Dickinson). Peripheral blood mononuclear cells were separated from venous blood by gradient centrifugation on Lymphoprep (Nycomed, Oslo, Norway) using standard techniques. Staining and fluorescence analysis were performed following identical procedures as per autologous tumour-infiltrating lymphocytes. Data obtained in double-fluorescence assays are reported as percentages of CD3$^+$ lymphocytes derived from either source, expressing the activation markers indicated.

Polymerase chain reaction assays

Total RNA was extracted from intact surgical biopsies, by the methods of Chomczynski and Sacchi[13], within 1 h of excision or sampling because of the extreme lability of the transcripts of the cytokine genes[14]. RNA (1 μg ml^{-1}) was reverse transcribed using Moloney murine leukaemia virus reverse transcriptase (200 units) in the presence of oligodeoxythymidine and deoxynucleotide triphosphates (all from BRL, Gaithersburg, Maryland, USA) according to the manufacturer's instructions. The resulting complementary DNAs (cDNAs) were assayed for the presence of cytokine transcripts in PCR assays performed in 20-μl volumes (Gene-Amp kit; Perkin-Elmer-Cetus, Norwalk, Connecticut, USA) in the presence of pairs of specific primers. Sequences of the primers used are shown in *Table 1*. Primers were designed to amplify sequences from different exons, to detect eventual

amplification of contaminating genomic DNA. PCR consisted of 35 cycles, each including 40 s denaturation at 94°C, 40 s annealing at 62°C and 1 min extension at 72°C. PCR products were subsequently run on 1·5 per cent agarose gels in Tris-buffered ethylenediamine tetra-acetic acid in the presence of ethidium bromide, and photographs taken on ultraviolet transillumination. Specificity of amplified transcripts was validated by correspondence to the expected size of cDNA sequences and by restriction mapping[15] (data not shown).

Results

Phenotypic analysis of tumour-infiltrating lymphocytes

Freshly derived tumour-infiltrating lymphocytes were evaluated and compared with autologous peripheral blood mononuclear cells for surface expression of activation markers in five patients under investigation. The proportion of $CD3^+$ tumour-infiltrating lymphocytes expressing CD69 or HLA-DR was significantly higher than that detectable in simultaneously sampled peripheral blood $CD3^+$ lymphocytes (mean(s.d.) $CD69^+$ 18(11) per cent in peripheral blood *versus* 68(25) per cent in tumour-infiltrating lymphocytes; $HLA\text{-}DR^+$ 8(5) *versus* 54(5) per cent). In addition, a surface marker characteristic of memory T cells (CD45RO) was found to be expressed in higher mean(s.d.) proportions of $CD3^+$ tumour-infiltrating lymphocytes than in autologous peripheral $CD3^+$ cells (75(21) *versus* 45(15) per cent).

Cytokine gene transcription

Total RNA extracted from freshly excised tumour biopsies was reverse transcribed and assayed in 35 cycles of PCR for the presence of transcripts of defined cytokine genes. *Figure 1* shows the results of a representative assay (patient 6). Transcripts for the β-actin gene could be amplified from cDNA derived from both peripheral blood mononuclear cells and tumour biopsy (*Figure 1a*), whereas IL-2 and IL-10 gene transcription was detected only in cDNA derived from the tumour biopsy (*Figure 1b* and *c*). *Table 2* shows the results. Transcription of the β-actin gene, tested as a positive control, was observed in all samples under investigation. In contrast, cytokine gene transcripts were never detectable in RNA from peripheral blood mononuclear cells ($n = 6$) or healthy renal tissue ($n = 5$). Transcription of IL-4 and IFN-γ genes was observed in only one biopsy, whereas IL-2 gene transcripts were detectable in five patients. IL-10 gene transcription was observed in seven biopsies.

Discussion

Tumour-infiltrating lymphocytes often express activation markers[6,7]. Antigen-driven triggering of T cells, however, would be expected to induce surface expression of activation and transcription of cytokine genes. Production of these soluble factors by immunocompetent cells plays a key role in the generation of an effective immune response.

Cytokine gene transcription was therefore examined in freshly excised tumour biopsies with lymphocyte infiltration, thereby avoiding possible cell separation and culture artefacts. The relatively low sensitivity of conventional Northern blot and *in situ* hybridization techniques did not allow demonstration of specific gene transcripts. Reverse PCR was therefore used. Renal cell carcinoma was chosen as this neoplasm may be a promising target for immunotherapy[16].

Transcription of IL-2, IL-4 and IFN-γ genes was studied because these cytokines are essential in the proliferation and functional activation of different T cell subsets[17–19]. IL-10 was studied because of its capacity to inhibit T cell proliferation and cytokine production[19–22].

The present results indicate that, despite infiltration by lymphocytes displaying surface activation markers and the use of a technique of extreme sensitivity, transcription of the cytokine genes under investigation shows wide variation in different renal cell carcinoma biopsies. In particular, transcription of IL-4 and IFN-γ genes was rarely detectable in lymphocyte-infiltrated neoplastic tissue. These data do not correlate with the pattern of cytokine gene transcription usually detectable on antigen receptor-triggered T cell stimulation *in vitro* or *in vivo*[14,15].

Regarding biopsies where cytokine gene transcription could be detected, PCR does not allow identification of the cells transcribing a given gene, and no further speculation is warranted. Irrespective of the cell type(s), however, where cytokine gene transcription takes place, these factors are able to affect the local immune response profoundly[9–12]. In particular, IL-2 and IL-10, whose gene transcripts are detected most frequently, display virtually opposite functional effects. IL-2 induces T lymphocyte proliferation and IFN-γ production; IL-10 inhibits these activities[21,22] and, together with TGF-β, is one of the two immune response inhibitory factors cloned to date. IL-2 and IL-10 have been reported to be produced by different T cell populations, albeit not clearly defined in their phenotypic profile[20]. The IL-10 gene has recently been found to be predominantly transcribed in ovarian cancer biopsies[23].

Taken together, the data suggest that patients with renal cell carcinoma do not show a homogeneous pattern of cytokine gene transcription. Interaction between tumour-infiltrating lymphocytes and neoplastic cells could result in different functional events. Further investigation is needed to address the issue of whether differential cytokine gene transcription has an influence on the clinical course of neoplastic disease or is of prognostic significance for immunotherapy procotols.

Localized argyria: a complication of the repair of inguinal hernia with silver filigree

D. W. Ellison, A. D. B. Chant*, T. A. Harrison† and J. M. Theaker

Correspondence to: Dr J. M. Theaker, Department of Histopathology, Southampton General Hospital, Tremona Road, Southampton SO9 4XY, UK

Localized argyria, the focal deposition of silver within tissues, is found most frequently in the oral mucosa following the accidental implantation of dental amalgam ('amalgam tattoo'). It has also been reported in the skin following accidental implantation by silversmiths, and with the use of silver earrings[1,2].

This paper reports a patient with localized argyria in the soft tissues of the inguinal canal following hernia repair with a silver filigree.

Case report

A 62-year-old man presented with a recurrent inguinal hernia, which had been repaired 30 years previously in another hospital in which the fashion was to insert a silver mesh. The patient had noticed a gradual breakdown in the repair over a 2-year period. At operation, a direct recurrence was repaired with nylon darn. All the tissues were firmly stained with a dense black substance; on closer inspection, fragments of metal were found. As much of the material as possible was removed for histological examination. There were no postoperative complications.

Routine histological sections showed a striking deposition of black granular refractile pigment in the walls of blood vessels, around nerves, and along collagen fibres in stromal tissue. These features are typical of argyria and reminiscent of the pattern of silver staining characteristic of the histochemical method for reticulin. There was a mild focal inflammatory reaction and only minor focal scarring.

Ultrastructural examination showed electron-dense deposits distributed around individual cells and along collagen fibres (*Figure 1*). Electron probe microanalysis of the involved tissue revealed large X-ray emissions corresponding to silver, and smaller emissions corresponding to selenium and sulphur.

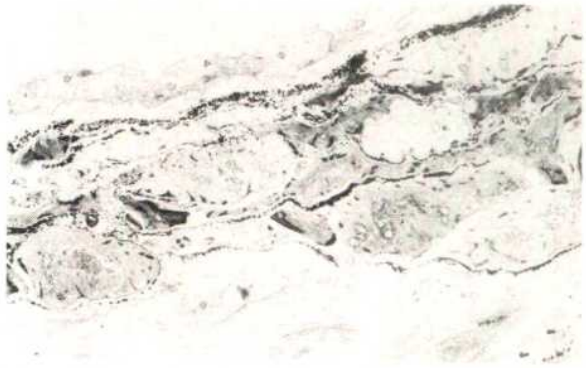

Figure 1 *Electron micrograph of a small blood vessel wall showing black granular silver deposits.* (*Original magnification* × *4400*)

Discussion

Localized argyria must be distinguished from generalized argyria, which typically follows oral ingestion of silver salts, local medicinal application to mucous membranes or occupational exposure to silver, producing systemic deposition of silver and diffuse cutaneous pigmentation. Localized argyria follows implantation of silver and most commonly occurs after the accidental introduction of dental amalgam into the mouth[1,2].

The repair of hernia with a silver filigree was described by McGavin[3] in 1909. The technique was frequently used at the Seamen's Hospital in Greenwich, the filigree mesh being made up on a jig by the theatre nurses in their spare time. It was thought that the irritant nature of the silver wire provoked an inflammatory reaction and fibrosis, and thus a stronger repair[4].

It is recognized that the silver filigree breaks down over the ensuing years with stress fractures, so that many surgeons must have been presented with cases to salvage. While reports of the results of secondary repair are available, there are no descriptions of black pigmentation in the surrounding tissues, although in the present authors' experience this is an invariable finding at re-exploration.

Documentation of this unusual and previously unrecorded phenomenon may alert surgeons to the nature of the pigmentation in the soft tissues of the inguinal canal after silver filigree hernia repair.

Faecal occult blood screening for patients with gastrointestinal symptoms

C. B. Falkson and T. Bates

Department of Surgery, William Harvey Hospital, Ashford, Kent TN24 0LZ, UK
Correspondence to: Mr T. Bates

A practical faecal occult blood (FOB) test as a screening tool for colonic pathology was first described by Greegor[1] in 1967. Many subsequent studies have examined the accuracy and value of FOB testing as a screening method for colonic carcinoma in an asymptomatic population[2–4]. Since the role of FOB testing in patients with gastrointestinal symptoms has not yet been clearly defined, the present study was undertaken to examine this question.

Patients and methods

All patients referred by their general practitioner with a history of lower abdominal pain or a change in bowel habit were screened to assess the urgency of investigation. On receipt of the practitioner's referral letter a Haemoccult (Roehm, Darmstadt, Germany)[5,6] FOB testing kit was posted to the patient. Those with obvious rectal bleeding and those with known colonic pathology were excluded from the study. Patients were not required to follow any dietary restrictions and were asked to provide stool specimens on 3 consecutive days, applied to Haemoccult slides. The slides were returned by post and analysed as soon as possible without rehydration[3,6]. All patients subsequently gave a full clinical history, and a clinical examination (including rectal examination and rigid sigmoidoscopy) was carried out. Further investigations were performed at the discretion of the clinician, but all patients with positive FOB tests underwent flexible colonoscopy or, occasionally, barium enema examination. The study was started in July 1985 and accrual closed in July 1990.

Results

Tests were posted to 518 patients; 458 were returned correctly completed, a compliance rate of 88 per cent. In all, 51 tests (11 per cent) were positive for FOB and 407 (89 per cent) negative. Colonic pathology was found in 32 of the 51 patients with positive tests, but no pathology has so far been detected in the remaining 19. Of the 407 patients with negative FOB tests, 39 have been found to have colonic pathology and 368 remain without known pathology. The median duration of follow-up is 4 years 7 months. The test has a specificity of 95 per cent with 19 false-positives, and the sensitivity is 45 per cent with 39 false-negatives.

Colonic pathology included 23 carcinomas, 22 polyps and 27 cases of histologically proven inflammatory bowel disease (IBD). One patient had both a polyp and IBD; haemorrhoids were not regarded as significant colonic pathology. Of the 23 patients with carcinoma, 19 had positive results with Haemoccult but there were four false-negative tests (sensitivity 83 per cent). In the group of 22 patients with polyps, only two had positive tests; of the 27 patients with IBD, 11 tested positive.

Four caecal tumours were detected, three of which gave positive Haemoccult results. Two carcinomas in the ascending colon, two in the left colon and six in the sigmoid all gave positive tests. Of nine rectal carcinomas, six tested positive. The interval between the last specimen and the test being carried out was a maximum of 6 (median 3) days in the false-negative cases. Haemoccult failed to detect 17 per cent of right-sided carcinomas and 33 per cent of rectal tumours.

Discussion

The high specificity (95 per cent) of FOB testing with Haemoccult compares favourably with values in the literature of 96–98 per cent[2–4]. The low overall sensitivity of 45 per cent reflects the very low sensitivity for polyps (9 per cent). It has been shown[5] that small polyps are less prone to bleeding and therefore less likely to be detected, but the sensitivity for carcinoma alone was much greater (83 per cent) and in line with results of other studies (68–80 per cent)[2,6,7]. One-third of rectal carcinomas were missed, a number similar to the findings of Thomas *et al.*[8]. These authors also found that 44 per cent of right-sided carcinomas were not detected; one-sixth of such tumours were missed in the present study. Symptomatic patients showed a much higher incidence of carcinoma in those testing positive for FOB (37 per cent *versus* 5–10 per cent for asymptomatic patients), but the predictive value for polyps was much lower (4 *versus* 20 per cent)[5].

This study shows that a positive Haemoccult test in the symptomatic patient is a strong indicator for urgent colonic investigation since the test has a high specificity, but a negative result does not adequately exclude colonic pathology in the symptomatic patient since the test has a low sensitivity. Haemoccult testing in the symptomatic patient serves only as a guide to the urgency of investigation.

Delay in the diagnosis and prognosis of carcinoma of the right colon

D. Goodman and T. T. Irvin

Department of Surgery, Royal Devon and Exeter Hospital, Barrack Road, Exeter EX2 5DW, UK
Correspondence to:
Mr T. T. Irvin

Of 152 consecutive patients with carcinoma of the right colon, 61 (40 per cent) suffered delays in treatment of more than 12 weeks from the onset of symptoms, with a mean delay of 48 weeks. The most common error was failure to initiate or complete the investigation of iron-deficiency anaemia (33 patients). False-negative barium enema investigations occurred in 16 cases. Patients with delays in diagnosis had survival rates not significantly different from those who presented early. Thirty-one patients with anaemia and no abdominal symptoms had a significantly higher survival rate than 30 presenting with abdominal symptoms, despite delays in treatment ($P < 0{\cdot}02$). Greater vigilance is required in the investigation of patients presenting with iron-deficiency anaemia.

Delays in the diagnosis or treatment of patients with carcinoma of the colon are more common with right-sided malignancy[1]. The clinical significance of such delay is uncertain and the outcome may be worse, better or no different from that of left-sided tumours[2–5].

This study examined incidence of delays in the treatment of patients with right-sided colonic cancer, reasons for the delay and effects on survival. Treatment of patients with colonic malignancy may be influenced by a number of variables, including speed of presentation to the general practitioner (GP) and subsequent referral to hospital, speed of diagnosis and any administrative delays affecting the admission when a diagnosis has been established. Average reported delays in the treatment of colonic cancer[1,6–8] range from 17 to 31 weeks but a significant proportion of patients are treated within 12 weeks of the onset of symptoms[9]. For the purpose of this study, 12 weeks was therefore accepted as the 'gold standard'.

Patients and methods

Case records were studied for 152 consecutive patients with carcinoma of the right colon admitted to a single surgical unit between 1979 and 1989. All patients had invasive adenocarcinoma of the colon arising proximal to the splenic flexure.

Two groups of patients were identified: group 1 comprised 91 patients undergoing treatment within 12 weeks of the onset of symptoms and group 2 61 patients who suffered varying degrees of delay. The mean (95 per cent confidence interval) time between the onset of symptoms and definitive treatment of carcinoma was 9·4 (8·1–10·7) weeks in group 1 and 48·1 (38·9–57·3) weeks in group 2.

Group 1 included 16 patients presenting with acute intestinal obstruction. Previous studies have shown that such patients have a short history and a poor prognosis[10,11]. Patients with obstruction were therefore excluded from this study.

Information was obtained concerning delays in treatment, clinicopathological variables and patient survival. Patients were followed for a minimum of 5 years after surgery. Information concerning survival was obtained from GPs when patients defaulted from follow-up. Two patients who left the area and were lost to follow-up have been presumed dead for statistical analysis. The median duration of follow-up was 60 (range 28–96) months. Survival was measured by life-table methodology[12,13] and the log rank test[14] used in the statistical analysis. Other clinical variables in subgroups of patients were compared by χ^2 analysis and Fisher's exact test.

Results

Causes of delay

Three identifiable causes of delayed treatment were found in group 2; ten patients had more than one source of delay. Late presentation to the GP occurred in 17 patients. Treatment was delayed by the practitioner in 18 patients, the most common error being failure to initiate investigation of iron-deficiency anaemia (16 patients). In 36 patients delay resulted from failure of hospital clinicians to diagnose colonic carcinoma. In 17 of these, iron-deficiency anaemia was not investigated or incorrectly attributed to an alternative benign disease such as peptic oesophagitis or duodenal ulceration. The patients presented in various hospital departments and the anaemia was usually an incidental finding during treatment of another illness. Review of the records showed that an authentic alternative cause of anaemia was proven in only three of the 17 patients (peptic oesophagitis in two, gastric leiomyoma in one).

Investigations performed by hospital clinicians included double- or single-contrast barium enema (102 patients), barium follow-through (11), barium meal or gastroscopy (49) and colonoscopy (19). In 19 patients the diagnosis was missed despite appropriate investigations (double-contrast barium enema in 16 patients, colonoscopy in three). Failures of colonoscopy were attributable to inability to reach the ascending colon or caecum.

Administrative delays in treatment were negligible. All patients were admitted to hospital within 2 weeks when the diagnosis of colonic carcinoma was established.

Clinical presentation

There was a significantly different incidence of anaemia, defined as a haemoglobin concentration below 11 g/dl, in the two groups of patients. Fifty-one (84 per cent) of the patients in group 2 and 41 (55 per cent) of those in group 1 presented with anaemia ($\chi^2 = 12{\cdot}87$, 1 d.f., $P < 0{\cdot}001$).

Table 1 *Patient details and location of primary tumours*

	Group 1 ($n = 75$)	Group 2a ($n = 31$)	Group 2b ($n = 30$)
Sex ratio (M:F)	36:39	10:21	13:17

It was possible to identify two subgroups in group 2. Thirty-one patients (group 2a) presented with vague malaise and symptoms attributable to anaemia; these patients had no specific abdominal or bowel symptoms. Thirty patients (group 2b) had significant abdominal symptoms including pain, altered bowel habit, or awareness of an abdominal mass.

Comparison of groups 1, 2a and 2b (Table 1)

There was no significant difference between the groups with regard to age and sex. The location of the primary tumour was based on the description given by the operating surgeon; there was a significantly higher incidence of tumours arising at or proximal to the hepatic flexure in group 2a compared with group 2b ($\chi^2 = 5{\cdot}06$, 1 d.f., $P < 0{\cdot}05$).

Treatment and hospital mortality (Table 2). There was no significant difference between the groups regarding the resectability of primary tumours and the incidence of palliative operations or hepatic metastases. The lower incidence of palliative procedures in group 2a was not statistically significant ($\chi^2 = 2{\cdot}21$, 1 d.f., $P > 0{\cdot}10$).

The incidence of perioperative blood transfusion and number of units of blood administered were similar in the three groups. For groups 1, 2a and 2b the proportions transfused were 77, 81 and 74 per cent respectively. The respective median (range) amounts transfused were 3 (2–12), 4 (2–12) and 3 (2–10) units.

Table 2 *Comparison of resection rates, palliative operations, hepatic metastases, hospital mortality and pathology*

	Group 1 ($n = 75$)	Group 2a ($n = 31$)	Group 2b ($n = 30$)
Primary tumour resected	72 (96)	31 (100)	27 (90)
Palliative operation	27 (36)	6 (19)	12 (40)
Hepatic metastases	13 (17)	4 (13)	6 (20)
Hospital death	3 (4)	0 (0)	2 (7)

No. at risk

Group 1	64	55	46	42	35	35	33	30	26	25
Group 2a	29	26	20	20	19	17	17	16	15	15
Group 2b	25	16	15	12	8	8	7	6	5	5

Figure 2 *Crude actuarial 5-year survival curves for patients in groups 1* (——), *2a* (– – –) *and 2b* (·····)

The 30-day hospital mortality rate was 4 per cent, with no significant difference between the groups. The causes of hospital death included pulmonary embolism (two patients), cardiac failure (two) and carcinomatosis (one).

Pathology (Table 2). There was a significantly lower incidence of Dukes' C tumours in group 2a compared with the other groups (group 2a *versus* group 2b: $\chi^2 = 6{\cdot}68$, 1 d.f., $P < 0{\cdot}01$; group 2a *versus* group 1: $\chi^2 = 4{\cdot}77$, 1 d.f., $P < 0{\cdot}05$).

Survival. For the crude 5-year survival curves, there was no significant difference between groups 1 and 2 (*Figure 1*). Analysis of the subgroups (*Figure 2*) revealed that patients in group 2a had a significantly higher survival rate than those in group 2b ($\chi^2 = 5{\cdot}73$, 1 d.f., $P < 0{\cdot}02$).

Discussion

Treatment of right-sided colonic cancer was delayed for more than 12 weeks in 40 per cent of the patients in this study. The factors involved in delay included late presentation to the GP, failure of the practitioner to investigate or refer the patient and failure of hospital clinicians to investigate or diagnose the illness. In a similar study, Fegiz *et al.*[5] found that 70 per cent of patients with carcinoma of the right colon suffered delays of more than 3 months, and Ratcliffe *et al.*[1] suggested that delayed presentation to the GP was the most common cause of delayed treatment of right-sided malignancies. It is probable that the relative contribution of patients, GPs and hospital clinicians in delayed treatment varies in different communities.

In the present study the most common error on the part of GPs was failure to determine the cause of iron-deficiency anaemia; this was also a frequent error during hospital management if the anaemia was an incidental finding during treatment of another illness. The association between iron-deficiency anaemia and occult carcinoma of the colon is well established[5–8,15–17], and it is surprising that this error persists.

There is a significant error rate in the diagnosis of right-sided colonic cancer by barium enema examination, false-negative results occurring in 7–26 per cent of patients[5,16]. The diagnosis of colonic cancer was missed in 16 of 102 patients undergoing barium enema examination in this study. Greater use of colonoscopy should reduce the incidence of diagnostic failure, although endoscopy failed for three patients in the present study.

Overall, the survival rate of patients who suffered delays in treatment was not significantly different from that of those who presented early. Previous studies have shown that there is a poor correlation between the duration of symptoms and the prognosis of colonic carcinoma[5,9,17]. The group of 61 patients suffering delays in diagnosis included two subgroups with very different prognoses. Patients presenting with anaemia and no abdominal symptoms had a relatively favourable prognosis. Thirty-one patients presented in this fashion and, despite delays in treatment, the 5-year survival rate of this group was higher than that of any other (*Figure 2*). The Dukes' stages of the tumours in this subgroup were more favourable; Fegiz *et al.*[5] have also noted that patients presenting with anaemia and no abdominal symptoms have a better prognosis. It appears that these tumours occur more often in the proximal part of the right colon (*Table 1*).

Would earlier diagnosis in patients with anaemia result in improved survival? It would appear that many of these patients have relatively slow-growing tumours with a low potential for spread. It is difficult to judge whether speedier diagnosis would improve the survival statistics. The incidence of error in diagnosis of carcinoma of the right colon is, however, a cause for concern and an important quality issue. GPs and hospital clinicians must exercise greater vigilance, particularly in the assessment of patients presenting with iron-deficiency anaemia. Such patients should receive a full investigation and clinicians should be aware of the potential errors in barium enema diagnosis of right-sided colonic malignancy.

Colonoscopic surveillance after curative resection for colorectal cancer

S. E. Patchett, H. E. Mulcahy and D. P. O'Donoghue

Gastroenterology and Liver Unit, St Vincent's Hospital, Dublin, Ireland

Correspondence to:
Dr S. E. Patchett, Department of Gastroenterology, St Bartholomew's Hospital, West Smithfield, London EC1A 7BE, UK

Colonoscopic surveillance after resection for colorectal cancer has been advocated to improve detection of anastomotic recurrence, and of synchronous and metachronous tumours. The benefit provided by colonoscopy remains unproven, and the best timing of examination is unclear. To determine the value of colonoscopy after curative resection for large bowel cancer, the efficacy of an endoscopic surveillance programme in the early detection of intraluminal bowel recurrence in a series of patients admitted with colorectal cancer was examined. Between April 1983 and December 1988, 132 patients underwent colonoscopy. Eight (6·1 per cent) were found to have intraluminal recurrence without evidence of extraluminal spread. Six of these recurrences were at the site of anastomosis and two represented metachronous tumour development. All of these patients were symptomatic at the time of diagnosis. In 15 patients (11·4 per cent), adenomatous polyps were discovered during the initial endoscopic examination. These results indicate that colonoscopic surveillance will rarely allow early detection of asymptomatic intraluminal bowel recurrence, but is valuable in the detection of synchronous lesions. Frequent surveillance is not justified in the early postoperative years and colonoscopy should probably be confined to a single procedure to exclude synchronous lesions.

Approximately 60 per cent of patients with colorectal cancer undergo potentially curative surgery[1]. Some 50 per cent of these patients will die in the ensuing 5 years, the vast majority from recurrence of disease[2]. The prognosis for patients with colorectal cancer is directly related to the stage of disease at the time of diagnosis[3]. Similarly, successful resection of recurrent and metachronous tumour is directly related to early detection[4]. Thus, it is generally believed that early detection and management of recurrence after curative resection can prolong life. For this reason it is argued that some form of follow-up is indicated for the remainder of the patient's life, with the aim of early detection of recurrence. As part of a detailed surveillance programme, colonoscopy has been advocated as a valuable method for detecting synchronous lesions and intraluminal recurrence[5–7], with better results than barium enema[8]. In common with other conditions for which colonoscopic surveillance has been advocated, such as adenomatous polyposis and long-standing colitis, the optimal timing of colonoscopic follow-up and its value in reducing mortality rates from development of cancer or recurrent disease remain in doubt[9,10]. Postoperative endoscopic surveillance might be expected to allow early diagnosis of anastomotic recurrence in addition to excluding synchronous or metachronous tumours. As the majority of anastomotic tumours occur within 2 years of surgery, intensive colonoscopic follow-up has been advocated during this period.

This study assessed prospectively the efficacy of an intensive surveillance programme over a 5-year period in a large series of patients with colorectal cancer. The aims of the study were to determine the value of intensive colonoscopic surveillance in the early detection of locally recurrent bowel carcinoma in patients who have undergone curative resection for colorectal cancer, and to determine the numbers of synchronous and metachronous tumours detected during this period.

Patients and methods

Between April 1983 and December 1988, 441 patients were admitted to this hospital with a diagnosis of colorectal cancer. Of these, 325 (73·7 per cent) underwent a potentially curative operation and were followed prospectively. Of the 325 patients, 132 (40·6 per cent) were enrolled into a strict endoscopic surveillance programme. Allocation to surveillance was not random but was based on the operating policy of the clinician responsible.

Patients on the surveillance programme underwent total colonoscopy after operation and subsequently at 6, 12, 18, 30 and 48 months. All patients also had a complete physical examination with measurement of the haemoglobin level and liver biochemistry. A detailed history of relevant symptoms such as abdominal pain, weight loss, bleeding or altered bowel habit was obtained at each visit. Particular care was taken to determine whether the symptoms had urged earlier presentation or whether the examination was purely part of the surveillance exercise. All positive findings at colonoscopy were carefully recorded, including the presence of adenomatous polyps and metachronous tumours. Data regarding age, sex, tumour stage and differentiation are given in *Table 1*.

Follow-up was complete in all 132 patients. The date and cause of all deaths were obtained from hospital records, or though direct contact with the general practitioner. The mean follow-up was 5·5 (range 3·2–8·8) years.

200	80	F	Ascending colon	Right hemicolectomy	C	22·1
310	81	F	Transverse colon	Right hemicolectomy	B	13·4
312	59	M	Rectum	Anterior resection	C	10·3
369	59	M	Rectum	Anterior resection	B	7·0

Results

At colonoscopy eight patients (6·1 per cent) were found to have recurrent cancer without evidence of extracolonic spread (*Table 2*). Six of these cancers were situated at the anastomosis; the remaining two were metachronous tumours, giving a metachronous tumour rate of 1·5 per cent. All eight patients were symptomatic at the time of follow-up colonoscopy. Three patients presented with altered bowel habit, three with rectal bleeding, one with fatigue related to anaemia and one with abdominal pain. Four patients underwent a second potentially curative procedure, three of whom are alive at least 3 years after the second operation.

Twenty-two benign adenomatous polyps were discovered endoscopically in 15 patients (11·4 per cent) over the study period. None of these patients underwent total colonoscopy before operation and all were asymptomatic at the time of diagnosis. In 14 of the 15 patients polyps were discovered at the first endoscopic examination after surgery. In one case a benign adenoma was discovered endoscopically 6 months after the initial normal examination.

Discussion

The optimum management of patients who have had successful resection for large bowel cancer remains in doubt. Several workers have recommended intensive screening programmes combining faecal occult blood testing, monitoring of carcinoembryonic antigen levels, computed tomography and colonoscopic examination in an effort to detect extraluminal and intraluminal recurrence at an early and curable stage[9,11–13]. Colonoscopy seems to be the most appropriate technique for the early detection of intraluminal recurrence; however, data regarding the precise benefit of intensive surveillance programmes and the frequency and timing of endoscopy are not currently available. By prospectively following a large group of patients enrolled in an intensive endoscopic surveillance programme, the present study attempted to answer some of these questions.

The results indicate that colonoscopic follow-up has little part to play in the early detection of anastomotic recurrence in asymptomatic individuals. The intraluminal recurrence rate of 6·1 per cent in this series is similar to those reported by others[7,14]. However, true asymptomatic intraluminal recurrence was not observed in the present study as, in all cases, symptoms rather than routine surveillance prompted a search for recurrent malignancy. This is in common with surveillance studies of long-standing colitis[15].

The four patients (3·0 per cent) in the present study who underwent a second potentially curative procedure, three of whom are alive at the time of writing, cannot be claimed to have benefited from colonoscopy. The failure to detect true asymptomatic bowel recurrence is consistent with the belief that most intraluminal recurrence begins in the extraluminal tissue and only secondarily invades the bowel wall[16]. The present findings agree with those of Cochrane *et al.*[11], and indicate that awareness and early investigation of symptoms is more appropriate than routine endoscopy of asymptomatic individuals.

The finding of adenomatous polyps in approximately 11 per cent of patients at the first postoperative colonoscopic examination confirms the view that synchronous neoplasms are commonly associated with colorectal cancer[17–19]. In the present series, however, these polyps were effectively cleared by the first postoperative procedure. (The single polyp found 6 months later at the time of follow-up endoscopy may well represent a 'missed' synchronous lesion rather than a metachronous neoplasm.)

This study indicates that an intensive colonoscopic surveillance programme after curative surgery for colorectal cancer does not result in earlier diagnosis of intraluminal bowel recurrence and therefore will not offer substantial benefit to the patient. The relative frequency of synchronous lesions confirms the importance of examining the whole colon either before or soon after operation to allow diagnosis of synchronous cancer and removal of adenomas. Further colonoscopy in the early postoperative years may safely be confined to symptomatic patients.

Visualization of the ureter during laparoscopic colonic resection

J. M. Sackier

Department of Surgery, University of California, San Diego Medical Center, 402 Dickinson Street, 8891 San Diego, California 92 103-9981, USA

Correspondence to: Dr J. M. Sackier

The growing enthusiasm for laparoscopic surgery following the success of laparoscopic cholecystectomy has led many surgeons to use this technique for colonic resection. In either right- or left-sided open colonic resection, a critical phase of the operation is to visualize the ureter clearly to avoid iatrogenic trauma. Using the laparoscopic technique, the absence of tactile sensation and the limited field of view make it more difficult to see the ureter throughout its entire course. This identification is especially problematic (though all the more important) in the presence of inflammation or tumour, as the normal anatomical position of the ureter may be distorted.

Surgical technique

Before commencing the laparoscopic operation, cystoscopy is performed and an illuminated 6-Fr ureteric probe (Karl Storz, Culver City, California, USA) 75 cm long (*Figure 1*) is inserted into the ureter on the same side as the colonic lesion. The probe is connected to a xenon light source by a screw fitting, and the laparoscopy is begun. When the colon has been elevated, the light source is turned on and the laparoscope source turned down. By this manoeuvre the surgeon is able to see the illuminated ureter in its entirety shining through the retroperitoneal structures. The procedure helps to localize this important structure while dissection of the lateral aspect of the colonic mesentery proceeds. Obviously this method is an adjunct to careful dissection, and it merely helps to ensure that the operation is completed safely.

Initial report from a Swedish multicentre study examining the role of preoperative irradiation in the treatment of patients with resectable rectal carcinoma

Swedish Rectal Cancer Trial

Correspondence to:
Dr L. Påhlman, Department of Surgery, Akademiska Sjukhuset, S-751 85 Uppsala, Sweden

Between March 1987 and February 1990, 1168 patients with resectable rectal cancer were recruited into a nationwide Swedish trial. Patients were randomly allocated to receive either preoperative irradiation (25 Gy in five fractions over 1 week) followed by surgery within 1 week, or surgery alone. In each group 454 patients underwent curative surgery. The groups were well matched for age, sex and surgical procedure. The postoperative mortality rates did not differ: 4 per cent after irradiation versus *3 per cent after surgery alone, but the postoperative mortality rate was significantly higher in patients treated with a two- rather than three- or four-portal technique (15* versus *3 per cent,* $P < 0{\cdot}001$*). More perineal wound infections were found in patients receiving irradiation (20* versus *10 per cent,* $P < 0{\cdot}001$*). No difference in the incidence of anastomotic dehiscence or other postoperative complication was found between the groups. Preoperative radiotherapy with a short-term high-dose technique can be delivered without major acute adverse effects, provided the irradiation technique is optimized.*

Irradiation as adjuvant treatment for patients with rectal cancer can be used before[1–4] and after[5–8] operation. Reduction of the local recurrence rate has usually been more pronounced after preoperative than postoperative treatment[9]. Meta-analysis, including all trials published before 1986, indicated a marginally positive effect on survival if radiotherapy was given (4·3 per cent)[10]. Most studies in this meta-analysis used low radiation doses unlikely to destroy micrometastases[11]. None of the more recent trials, in which significant reductions in local recurrence rate have been noted, was included in the analysis.

It is not uniformly accepted that preoperative radiotherapy can be delivered without a major negative influence on the outcome of subsequent surgery. This trial was initiated to explore whether short-term high-dose preoperative irradiation given with an optimized technique to patients aged 79 years or less with resectable rectal carcinoma could reduce the incidence of local recurrence without increasing the postoperative mortality rate, and increase the long-term survival. This initial report describes the trial design, patient characteristics and surgical outcome, focusing on the immediate postoperative effects of treatment.

Patients and methods

Randomization

Randomization in blocks of four or six patients was carried out by telephone to the six different Swedish regional oncological centres. The numbers in the blocks were unknown to the investigators. Patients were stratified for hospital and randomly allocated to receive preoperative irradiation for 1 week followed by surgery within the next week, or surgery with no additional radiotherapy or other anticancer treatment until recurrence occurred.

Sample size

To reduce the local recurrence rate from 20 to 10 per cent, 475 patients had to be recruited to detect the difference with 90 per cent probability and a 5 per cent significance level. To detect an increase in postoperative mortality rate from 2 to 5 per cent, 750 patients had to be included (90 per cent probability, 5 per cent significance level). To show an increase in survival rate of 10 per cent (from 50 to 60 per cent) after 5 years with 80 per cent probability and a 5 per cent significance level, 750 patients undergoing curative resection had to be recruited. Allowing for a 10 per cent drop-out rate, and that approximately 20 per cent of patients would have generalized disease at surgery or undergo locally non-curative resection, at least 1100 patients had to be included.

Patients

Between March 1987 and February 1990, 1168 patients with resectable rectal carcinoma in whom an abdominal procedure was planned were recruited into the trial.

Inclusion criteria were: histopathologically proven adenocarcinoma; tumour situated below the sacral promontory as shown on a side projection on barium enema; age 79 years or younger; and informed consent with approval of the local ethical committee. Exclusion criteria were: locally irresectable tumour; patients with a small tumour, in whom local surgical treatment was intended; known generalized disease; previous radiotherapy to the pelvis; and other malignant disease, except squamous cell carcinoma of the skin.

Twenty-one patients were excluded because they did not fulfil the inclusion criteria, leaving 1147 correctly assigned (*Table 1*). The sex and age distributions were similar in the two groups. The median (range) age in the group receiving irradiation was 69 (27–79) years for women and 68 (31–79) years for men. The corresponding figures for patients given surgery alone were 67 (31–79) and 67 (33–79) years. The type of surgery performed in each group is shown in *Table 2*.

Irradiation technique

The target volume included the anal canal, the primary tumour, the mesorectal and presacral nodes, the lymph nodes along the internal

iliac artery, the lumbar lymph nodes up to the level of the upper border of the fifth lumbar vertebra and the lymph nodes at the obturator foramen. The treatment was delivered with three portals as previously described[12] with the patient in a prone position, or with a four-portal 'box' technique with the patient lying supine.

The protocol tumour dose was 25 Gy in five fractions over 1 week. The treatment was individually planned in each patient and given with 5–16-MV photons. The dose was defined at the intersection of the central axes of the three or four beams. The protocol recommended a treatment time from Monday to Friday giving a cumulative radiation effect (CRE) value of 15·1. Treatment started on other days resulted in a slightly lower CRE of 14·5. The CRE was calculated according to Kirk *et al.*[13] with correction for late effects as described by Turesson[14].

Surgery and histopathology

Standard surgical procedures were used with the choice of anterior resection or abdominoperineal excision determined by the surgeon. A procedure was considered locally curative if the surgeon and histopathologist reported free margins, even if the bowel was perforated at surgery. Locally uncertain curative surgery was defined as either the surgeon or pathologist reporting a questionable margin. In all other cases, the treatment was reported as locally non-curative.

Postoperative mortality was calculated as death in hospital and that within 30 days, facilitating comparison with other reports. Complications of surgery were prospectively assembled and registered.

Resection specimens were examined by a local pathologist and the tumour classified according to Dukes' original staging system. The number of examined and tumour-infiltrated lymph nodes were recorded, and the pathologist classified the resection as locally curative, uncertain curative or locally non-curative.

Surgery was considered curative when there were no distant metastases and the resection was locally curative.

Statistical analysis

Differences in proportions were assessed using χ^2 analysis and differences between means with Student's t test, with a significance level of $P < 0{\cdot}05$. Analyses of postoperative mortality rates were based on all eligible patients, whereas postoperative morbidity was analysed only in those who underwent resection. All comparisons between treatment groups were on the basis of intention to treat.

Results

Radiotherapy

Seventeen patients (3 per cent) had no radiotherapy although they were allocated to that treatment group, and five patients (1 per cent) received less than 25 Gy. Radiotherapy started on a Monday (i.e. was delivered over 5 consecutive days) for 424 patients and was delivered over 7 days in 102. Only 29 patients (5 per cent) had a treatment period longer than 7 days. The operation was performed within 3 days in 202 patients (36 per cent), after 4–7 days in 287 (52 per cent), after 8–14 days in 36 (7 per cent) and later than 15 days in 30 (5 per cent). Treatment was given with a three- or four-portal technique in 175 and 332 patients respectively. Forty-eight patients were irradiated with a two-portal technique using one frontal and one dorsal portal. Most patients experienced no adverse effects during irradiation but some had bilateral pain in the buttocks. This effect was reversible in all but one patient, who had persistent pain for more than 2 years.

Surgery and histopathology

Table 3 shows the local stage according to surgical procedure. A difference in Dukes' stage between the two treatment groups was found ($\chi^2 = 11{\cdot}8$, 3 d.f., $P = 0{\cdot}008$). The distribution of distant metastases was similar in the two groups (*Table 1*), giving 454 patients treated curatively in each group.

Postoperative mortality

The hospital mortality rate was 3 per cent for patients receiving surgery alone and 4 per cent for those given irradiation ($P = 0{\cdot}31$). The corresponding 30-day mortality rates were 2 and 2 per cent respectively. For patients randomized to irradiation, the hospital mortality rate was lower among those treated according to the protocol with three or four portals (3 per cent) than in those treated with a two-portal technique (15 per cent, $P < 0{\cdot}001$) or no irradiation (12 per cent, $P = 0{\cdot}13$). There was no significant difference in postoperative mortality rate between treatment with three *versus* four portals (3 *versus* 2 per cent, $P = 0{\cdot}98$).

The postoperative mortality rate increased with age, particularly for patients undergoing non-curative surgery (*Table 4*). Data on postoperative mortality with respect to surgical procedure are given in *Table 5*. Sex, time from irradiation to surgery and radiation energy ($\leqslant 8$ or > 8 MV) did not influence the postoperative mortality rate. The causes of death are given in *Table 6*.

Postoperative morbidity

Of the patients receiving irradiation followed by anterior or abdominoperineal resection, 56 per cent had no complications of surgery (*Table 7*). This figure was 66 per cent for patients receiving surgery alone ($P = 0{\cdot}001$). The difference was caused by an increased number of perineal wound infections after

*Values are mean (range). †Student's t test

abdominoperineal resection in patients given radiotherapy (20 *versus* 10 per cent for surgery alone, $P < 0{\cdot}001$). Of patients receiving irradiation, 11 per cent developed anastomotic dehiscence; the corresponding value for those undergoing surgery alone was 8 per cent ($P = 0{\cdot}3$). No differences in complication rates were detected if two, three or four portals were used, nor using different energies (≤ 8 or >8 MV).

Postoperative hospital stay

The mean (range) hospitalization time for patients undergoing surgery alone was 19 (7–101) days compared with 22 (7–121) days for those given irradiation ($P < 0{\cdot}001$) (*Table 8*). This difference was found mainly in those operated on with abdominoperineal resection ($P < 0{\cdot}001$); no significant difference was seen for patients treated by anterior resection. The mean postoperative stay in those undergoing abdominoperineal resection who had a perineal wound infection was 31 days after irradiation and 30 days after surgery alone ($P = 0{\cdot}7$). The corresponding figures for those without perineal wound infection were 24 and 20 days respectively ($P < 0{\cdot}001$). There was also a difference in hospital stay for those operated on with an exploratory laparotomy ($P < 0{\cdot}05$).

Discussion

In one Swedish trial[2], the short-term high-dose preoperative radiation regimen used in the present study reduced the proportion of local recurrences, and in another Swedish trial[9] it decreased this proportion to the same extent as high-dose postoperative radiotherapy. In neither trial was survival significantly influenced. There has, however, been some concern regarding acute adverse effects of the radiation regimen used in the present study. A significantly increased postoperative mortality rate was found in the Stockholm–Malmö trial[2], but not in the Uppsala study[9], using the same irradiation dose. The reasons for this difference may relate to the different irradiation techniques used. In the Stockholm–Malmö trial one dorsal and one frontal portal were used, with the patient in the supine position. In the Uppsala study, three dorsal portals were employed, with the patient in the prone position. The use of three or more portals considerably reduces the risk of surrounding organs not containing tumour cells obtaining the high radiation dose prescribed for the tumour target. Most patients died from cardiovascular disease rather than from infectious complications or causes immediately related to the irradiated area. These findings could indicate that irradiation of a large abdominal volume using a relatively high dose followed by immediate surgery might be detrimental, particularly to elderly patients.

In the present trial, patients irradiated as intended, with three or four portals, showed no increase in postoperative mortality rate over those receiving only surgery (3 per cent in both groups). In the minor proportion of patients not irradiated according to recommendations in the protocol, i.e. using the two-portal technique as in the Stockholm–Malmö trial, a high postoperative mortality rate of 15 per cent was noted. These results support the concept that a large irradiated volume may be detrimental. The follow-up is too short to evaluate late adverse effects, but none was found in an evaluation of patients treated with preoperative irradiation in the Uppsala trial[15].

In the present trial, as in others[1–3,9], the number of perineal wound infections increased for abdominoperineal resection with preoperative radiotherapy. There were no other differences in complication rate except a slightly prolonged hospital stay after surgery for patients given preoperative radiotherapy.

This study demonstrates that preoperative radiotherapy to a relatively high dose can be delivered with no major early adverse effects. The results indicate that the technique must be optimized so that unnecessarily large volumes are not irradiated, otherwise detrimental effects might outweigh possible benefits.

A study was performed to determine the in vitro *response of the longitudinal smooth muscle layer (conjoined longitudinal coat) of the human anal canal to cholinergic and adrenergic stimulation, and to compare this with similar features of the internal anal sphincter (IAS) and rectal smooth muscle. Tissue was obtained from abdominoperineal and anterior resection specimens, and strips of muscle mounted for isometric tension recording in superfusion organ baths. Both conjoined longitudinal coat and IAS strips generated and maintained spontaneous myogenic tension (mean(s.e.m.) 0·10(0·01) and 0·48(0·04) g per mg tissue respectively), whereas equivalent rectal smooth muscle did not. Stimulation of muscarinic (cholinergic) receptors caused contraction of strips from the conjoined longitudinal coat and rectal smooth muscle layers in a dose-dependent manner (10^{-7}–10^{-4} mol/l); however, IAS strips relaxed (10^{-6}–10^{-4} mol/l). Activation of α-adrenergic receptors in conjoined longitudinal coat and IAS strips produced concentration-dependent contraction (10^{-7}–10^{-4} mol/l). In comparison, rectal smooth muscle relaxed. All muscle layers relaxed in response to β-adrenoceptor stimulation. These data indicate that in the anal canal both the conjoined longitudinal coat and IAS are specialized sphincteric smooth muscles.*

There are two predominant smooth muscle structures within the anal canal: the internal anal sphincter (IAS) and the conjoined longitudinal coat. The anatomy of these structures has been described previously and is well reviewed[1,2]. The IAS is the terminal part of the circular smooth layer of the gastrointestinal tract and consists of fascicles of smooth muscle fibres ensheathed in connective tissue. The conjoined longitudinal coat, on the other hand, is the most caudal extension of the longitudinal muscle layer of the gut and consists of much less smooth muscle than the internal sphincter. At the pelvic floor, the conjoined longitudinal coat is joined by some (scant) striated muscle fibres from the levator ani (pubococcygeus) and then traverses the anal canal between the internal and external sphincters. As it descends, it becomes progressively fibroelastic and gives off several septa which ramify through both the IAS and the lowermost part of the external sphincter, to gain attachment to the dermis of the anal and circumanal skin. In addition, other septa pass outward, away from the anal canal, to blend with the connective tissue of the ischiorectal fossa and perianal space.

Much is known about the activity of the IAS. It is recognized that it plays an important role in anorectal continence, being principally responsible for the generation and maintenance of resting anal canal pressure[3,4]. The IAS contracts spontaneously, developing a high degree of myogenic tone, and relaxes to allow the passage of stool, to permit anorectal sampling and in response to rectal distension. The conjoined longitudinal coat can now be imaged by endoanal ultrasonography and is seen during intersphincteric dissection of the anal canal but, compared with the IAS, little is known about its behaviour. Its true function is unknown; indeed, as far as the authors are aware, the activity of the human conjoined longitudinal coat has not been examined previously.

This paper describes studies in which aspects of the behaviour of the two smooth muscle layers of the anal canal were compared *in vitro*. In particular, their spontaneous activities and how these are modified by cholinergic and adrenergic drugs were examined. These agents were chosen to mimic the actions of important neurotransmitters in the gastrointestinal tract that are released from intrinsic enteric neurones as well as from extrinsic nerves of the sympathetic and parasympathetic nervous systems. To characterize the behaviour of anal canal smooth muscle further, similar experiments were also carried out on the equivalent muscle layers of the rectum.

Patients and methods

Sphincter tissue was obtained from patients undergoing abdominoperineal resection of the rectum and anal canal for low rectal carcinoma (three men, four women; median age 65 (range 62–75) years). Rectal smooth muscle was derived from this source and from patients with more proximal rectal tumours undergoing low anterior resection with coloanal anastomosis (four men; median age 63 (range 60–65) years). To maintain consistency in tissue collection, internal sphincter and conjoined longitudinal coat smooth muscle was obtained from adjacent sites in the anal canal, the most cranial part of which was defined by the attachment of the striated muscle of the pelvic floor. Rectal circular and longitudinal smooth muscle was acquired from the 'body' of the rectum, which was assumed to be midway along the craniocaudal axis of the resection specimen.

Once suitable tissue had been selected, the epithelium and submucosa were removed with the aid of a dissecting microscope. Adjacent strips containing parallel smooth muscle bundles were then excised, each measuring approximately 1 × 1 × 10 mm and weighing

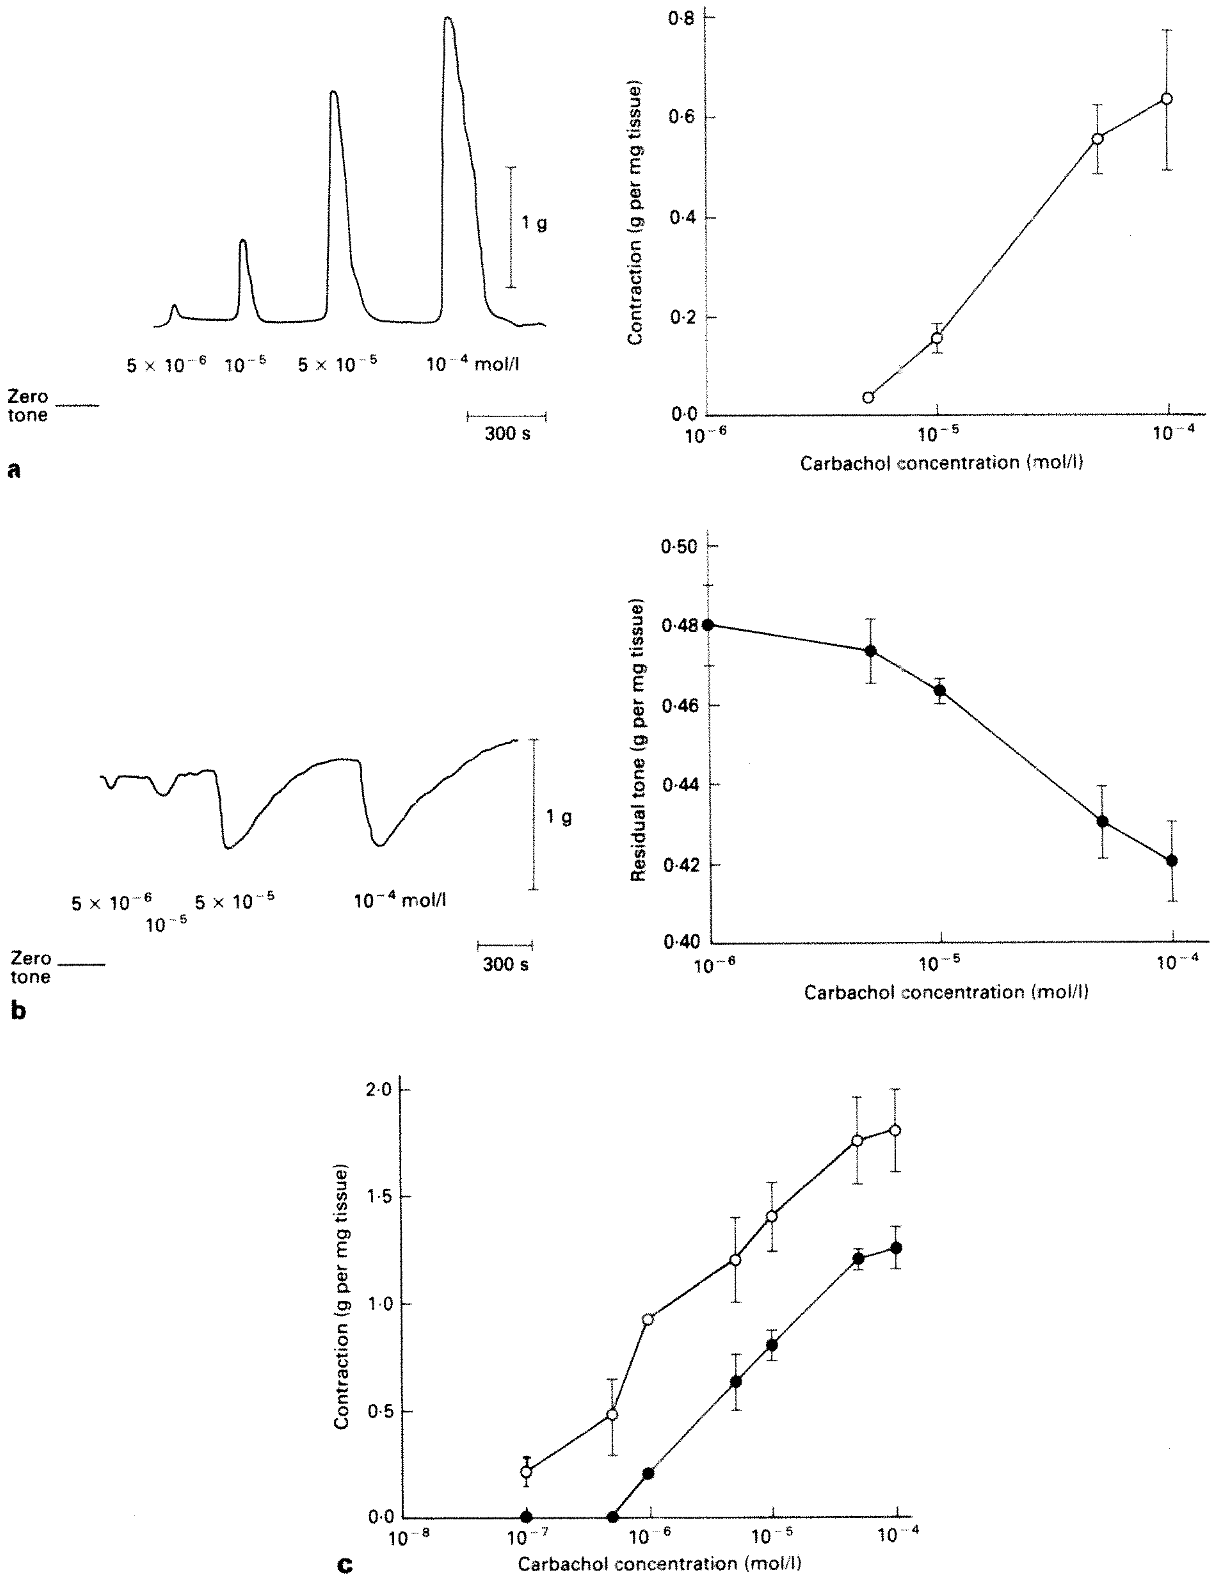

Figure 1 **a** *Response of smooth muscle strips from the conjoined longitudinal coat to increasing concentrations of carbachol, illustrated by a characteristic trace and a dose–response curve. Each point represents the mean(s.e.m.) of all strips tested* (n = *18*(*3*)). *Zero tone in this and subsequent figures represents the tension present in calcium-free solution.* **b** *Response of smooth muscle strips from the internal anal sphincter to increasing concentrations of carbachol, illustrated by a characteristic trace and a dose–response curve* (n = *30*(*6*)*; values are mean*(*s.e.m.*)). *Residual tone is the tension remaining in the strips after application of the drug.* **c** *Responses of longitudinal* (○) *and circular* (●) *smooth muscle strips from the rectum to increasing concentrations of carbachol* (n = *18*(*4*)*; values are mean*(*s.e.m.*))

5–8 mg. Threads were tied at each end of the strips, which were mounted for isometric tension recording in superfusion organ baths (capacity 0·2 ml). The strips were continuously superfused with Krebs solution (37°C) at a rate of 1 ml/min. Drugs and other agents being investigated were added to the Krebs solution before it was placed in the bath. The apparatus allowed six strips to be studied simultaneously. Tension was measured using Pioden transducers (Pioden Controls, Canterbury, UK) and recorded on a six-channel Teckman pen recorder (Teckman Electronics, Leamington Spa, UK). The strips were placed initially under 1·0 g resting tension and allowed to equilibrate for at least 1 h before the start of experiments. For calculation of spontaneous and stimulated tension, the tension present in strips held in calcium-free solution was regarded as the baseline (zero) and was subtracted from the observed tension.

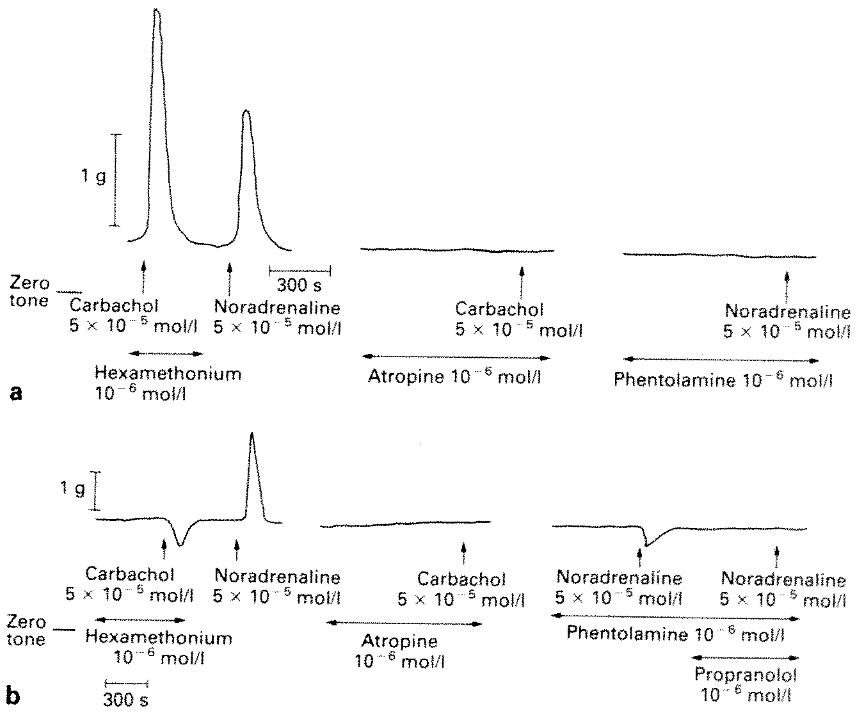

Figure 2 *Analysis of the actions of carbachol and noradrenaline on an isolated strip of human* **a** *conjoined longitudinal coat and* **b** *internal anal sphincter. Similar responses were seen in all strips tested* (n = *12(2)*)

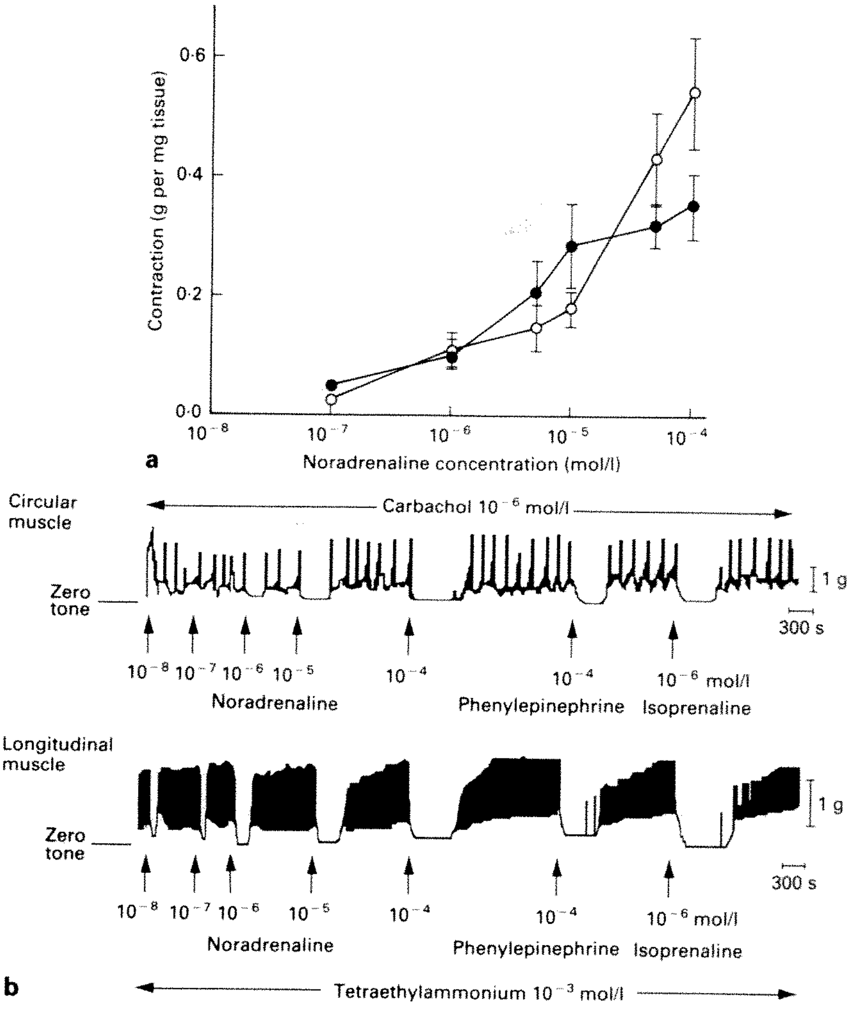

Figure 3 **a** *Response of the conjoined longitudinal coat* (n = *18(5)*; ○) *and internal anal sphincter* (n = *18(3)*; ●) *to increasing concentrations of noradrenaline. Values are mean(s.e.m.).* **b** *Response of the circular and longitudinal muscle layers of the rectum to increasing doses of noradrenaline, phenylephrine* (*an α-adrenoceptor agonist*) *and isoprenaline* (*a β-adrenoceptor agonist*). *Carbachol and tetraethylammonium were applied to increase basal tone and stimulate spontaneous activity, so revealing the inhibitory actions of the sympathomimetic agents. Similar responses were seen in all 12(2) preparations studied*

Standard Krebs solution was equilibrated with 97 per cent oxygen–3 per cent carbon dioxide. Drugs and agents used were: carbamylcholine chloride (carbachol); hexamethonium bromide; isoprenaline sulphate; phentolamine hydrochloride; phenylephrine hydrochloride; atropine sulphate; tetraethylammonium chloride; noradrenaline; propranolol hydrochloride; and tetrodotoxin.

Experimental results are expressed as mean(s.e.m.) and, where appropriate, statistical differences assessed with Student's unpaired t test. $P < 0{\cdot}05$ was considered significant. Numbers (n) are given in the form $x(y)$, where x is the number of strips and y the number of patients.

Results

Spontaneous tension

During the period of equilibration, muscle strips taken from the IAS contracted spontaneously and developed a mean(s.e.m.) steady-state tension of 0·48(0·04) g per mg tissue (n = 30(6)). By comparison, those from the conjoined longitudinal coat relaxed spontaneously and maintained a mean(s.e.m.) steady-state tension of only 0·10(0·01) g/mg (n = 24(5)). This difference was highly significant ($P < 0{\cdot}001$). In neither case did the nerve toxin tetrodotoxin (3×10^{-6} mol/l) reduce spontaneous tension, confirming that the effect was myogenic in origin. Both layers of smooth muscle from the rectum (n = 24(4)) completely relaxed in the organ baths and had no tension once the steady state was achieved (equal to that present in calcium-free solution).

Responses to cholinergic agonist

Carbachol is a cholinergic agonist; *Figure 1* shows the response of the various muscle strips to a 10-s application of this agent. Samples from the conjoined longitudinal coat (n = 18(3)) and both layers of the rectum (n = 18(4)) contracted in a dose-dependent manner on addition of carbachol, whereas those from the IAS relaxed (n = 30(6)). The responses were not modified by hexamethonium (10^{-6} mol/l) (n = 12(2)), a ganglionic (nicotinic) cholinergic receptor antagonist, but they were antagonized by atropine (10^{-6} mol/l) (n = 12(2)), which blocks the action of cholinergic agents at muscarinic (cholinergic) receptors (*Figure 2*).

Responses to adrenergic agonist

Noradrenaline is the principal neurotransmitter released by postganglionic sympathetic nerves. Its application to muscle strips from the conjoined longitudinal coat (n = 18(5)) and internal sphincter (n = 18(3)) for 20 s caused dose-dependent contractions (*Figure 3a*). In the presence of phentolamine, an α-adrenoceptor antagonist, the response of conjoined longitudinal coat strips to 5×10^{-5} mol/l noradrenaline was abolished (n = 12(2)); however, in the case of IAS strips, relaxation was revealed (n = 12(2)) (*Figure 2*). This modified internal sphincter response was abolished on addition of propranolol, a β-adrenoceptor antagonist (n = 6(2)). Both IAS and conjoined longitudinal coat strips relaxed in response to application of isoprenaline, a β-adrenergic agonist (10^{-9}–10^{-6} mol/l).

In their relaxed state, strips from neither layer of rectal smooth muscle responded to noradrenaline (n = 18(3)). If, however, tension and activity were raised by the addition of carbachol to circular strips (n = 12(2)) and tetraethylammonium to longitudinal strips (n = 12(2)), then noradrenaline was seen to have an inhibitory effect on both the frequency and amplitude of the resulting contractions. This inhibition could be reproduced by stimulation of both α- and β-adrenoceptors with phenylephrine or isoprenaline respectively (n = 12(2) for each layer; *Figure 3b*).

These results are summarized in *Table 1*.

Table 1 *Summary of results*

		Agonist effect	
	Tone	Cholinergic	α-Adrenergic
Internal anal sphincter	High	Relaxation	Contraction
Conjoined longitudinal coat	Low	Contraction	Contraction
Rectal smooth muscle	Absent	Contraction	Relaxation

Discussion

The importance of the smooth muscle components of the anal canal is becoming increasingly apparent[5] and a greater understanding of their properties will provide new insight into the mechanisms of continence and defaecation, and how they are altered to produce clinical syndromes such as anorectal incontinence. Such knowledge might also suggest novel ways in which sphincter activity can be altered pharmacologically.

Some aspects of human conjoined longitudinal coat and IAS muscle behaviour are similar. First, isolated strips from both layers generate and maintain spontaneous myogenic tension, although this is much less in the conjoined longitudinal coat. The mechanism responsible for this has been explored by Bouvier and Gonella[6]. Using the sucrose gap technique, they examined tension and electrical activity in circular and longitudinal muscle taken from the anal sphincter area of the cat. In the former they noted slow variations in smooth muscle membrane potential called slow waves. In longitudinal muscle, spike potentials were superimposed on these. Each slow wave (internal sphincter) or spike potential (conjoined longitudinal coat) was associated with an increase in basal tension. Both slow waves and tension disappeared in calcium-free solution and in the presence of manganese ions, indicating that electromechanical coupling was calcium dependent. Research is required to confirm whether human anal canal smooth muscle behaves in a similar fashion and also to elucidate further the processes responsible for spontaneous tone. This area is likely to be fertile ground for the pharmacological manipulation of sphincter activity in the future.

The conjoined longitudinal coat and IAS are also similar in their response to exogenous adrenergic agonists. Both contract when α-adrenoceptors are stimulated, but relax when β-adrenoceptors are stimulated. This behaviour is characteristic of sphincter-specialized gastrointestinal smooth muscle[7]. Non-sphincteric gastrointestinal smooth muscles, as evidenced by the response of both layers of rectum, relax when either of these receptors is stimulated[7]. The differences between responses of the circular smooth muscles of the anal canal and rectum have been described previously in the cat[8] and vervet monkey[9]. The mechanisms that underlie these differences in activity were not determined in the present study.

In its response to exogenous cholinergic agonists, the conjoined longitudinal coat contracts and so behaves like both layers of the rectum and smooth muscle elsewhere in the gastrointestinal tract[7]. The dose-dependent relaxation of the internal sphincter to muscarinic receptor activation is therefore outstanding, and currently not explained. It has been noted previously[10] and could result from a direct cholinergic effect on IAS smooth muscle. It is also conceivable, however, that cholinergic stimulation releases another agent that produces the ultimate mechanical response. Similar relaxations are seen in some vascular smooth muscle preparations, where they are thought to be mediated by the release of nitric oxide from endothelial cells[11,12]. Nitric oxide is a recently discovered endogenous bioactive substance with many functions[13–15], including that of an inhibitory neurotransmitter within the gastrointestinal tract[16]. As intrinsic nerves and small blood vessels are present in the muscle strips used in these studies, it is possible that nitric oxide mediates IAS relaxation in response to cholinoceptor stimulation. Further research is required to explore this phenomenon as it clearly has an important bearing on understanding of how enteric and parasympathetic cholinergic nerves interact with the internal sphincter.

Caution is required when interpreting the findings of *in vitro* experiments. However, on the basis of the present results, we believe that the conjoined longitudinal coat, like the IAS, shows true sphincter specialization both in its ability to generate spontaneous tension and in its pharmacological behaviour. No firm conclusions can be made about the function of the conjoined longitudinal coat, but the present findings are consistent with previous suggestions that it helps to maintain the structural integrity of the anal canal throughout the defaecation cycle, and contracts during the passage of faeces to shorten the anal canal and evert the anal margin[17,18]. *In vivo* as well as further *in vitro* experiments are required to confirm this suggestion and to explore the actions of the conjoined longitudinal coat more fully.

Physiological and histochemical adaptation of the electrically stimulated gracilis muscle to neoanal sphincter function

B. D. George, N. S. Williams, J. Patel, M. Swash* and E. S. Watkins†

*Departments of Surgery, †Neurosurgery and *Pathology, The Royal London Hospital, London E1 1BB, UK*

Correspondence to:
Mr B. D. George

The physiological and histochemical characteristics of the gracilis muscle were studied in 19 patients undergoing electrically stimulated gracilis neosphincter construction. Indications for surgery were faecal incontinence (n = *11*) *and reconstruction following sphincter excision or congenital absence* (n = *8*). *Transposition of the gracilis muscle around the anal canal followed by chronic low-frequency electrical stimulation was associated with a shift in the frequency–response curve and a prolongation of the time-course of individual muscle twitches suggestive of transformation to a slow-twitch fatigue-resistant type. Temporary cessation of electrical stimulation resulted in a reversal of the frequency–response changes. Muscle biopsies taken before and a median of 80* (*range 49–137*) *days after transposition and low-frequency electrical stimulation indicated a significant increase in the proportion of type 1 fibres and a significant decrease in their diameter. These results show that the human gracilis muscle is capable of physiological and histochemical adaptation to long-term neosphincter function.*

Several skeletal muscle types have been used to augment or replace the anal sphincter musculature[1–5]. Pickrell *et al.*[3] first described the use of gracilis, which has subsequently become the muscle of choice for this purpose. The results have been unsatisfactory[6], at least in part because fast-twitch fatigable muscles have been used to perform a function normally carried out by those of slow-twitch fatigue-resistant type.

Recent advances in muscle physiology[7,8] have demonstrated in experimental animals that the properties of skeletal muscle may be modified by various stimuli. Salmons and Vrbova[9] first showed that continuous low-frequency electrical stimulation transforms fast-twitch fatigable muscle into the slow-twitch fatigue-resistant type. Such electrical stimulation has been applied to the gracilis sling operation in an attempt to achieve the fatigue resistance appropriate for sphincter function, with encouraging early clinical results[10,11]. There is, however, little evidence to demonstrate that electrical stimulation can transform fast-twitch human muscle. Similarly, the effects of muscle transformation and altered configuration, essential for neoanal sphincter construction, are unknown. The aim of this study was to compare the physiological and histochemical properties of the human gracilis muscle before and after construction of an electrically stimulated neoanal sphincter.

Patients and methods

Patients

Nineteen patients (14 female, five male; median age 48 (range 16–76) years) underwent gracilis neosphincter construction between December 1989 and June 1991, and have been followed for a median of 20 (range 8–26) months. Eleven patients (group 1) had faecal incontinence for a variety of reasons and eight (group 2) underwent neosphincter formation as part of a reconstructive procedure following sphincter excision or because of a congenital absence of sphincter muscle (*Table 1*). Details of the surgical procedures have been described previously[10]. All patients in the study underwent a preliminary vascular delay procedure a median of 5 (range 1–24) weeks before transposition to enhance the viability of the gracilis muscle during transposition and electrical stimulation[12].

Methods

The transposed gracilis was stimulated electrically with a totally implantable stimulator (initially Itrel; Medtronic, Minneapolis, Minnesota, USA, recently NICE implant; Neuromed, Fort Lauderdale, Florida, USA), programmed transcutaneously using a portable programmer. Stimulation was started more than 6 days after operation (median 15·5 (range 7–50) days). The nerve to the gracilis neosphincter was stimulated at its supramaximal voltage (range 0·25–6·0 V) with a pulse width of 210 μs to ensure utilization of all available motor units. Two different patterns of low-frequency stimulation were employed. In seven patients the neosphincter was stimulated continuously at 2 Hz; in 12 stimulation was intermittent at between 10 and 25 Hz. The 'on' times (4–10 s) and 'off' times (1–10 s) were altered at approximately 2-weekly intervals, such that the proportion of time that the muscle was activated was progressively increased. Once satisfactory neosphincter function was demonstrated by dynamic proctography[13] the covering stoma was closed (range 9–26 weeks). After stoma closure the muscle was stimulated at its supramaximal voltage using a stimulus pulse width of 210 μs and frequency of 10 Hz continuously in all cases.

Physiological measurements

Preoperative. Preoperative anal canal pressures were measured with a water-filled microballoon 6 mm in diameter connected to a pressure transducer, amplifier and chart recorder. The microballoon was inserted into the anal canal and the pressure recorded at 1-cm stations from 5 to 0 cm from the anal verge, at rest and during a maximum voluntary squeeze. The maximum basal pressure and

maximum achieved pressure were recorded. The maximum squeeze pressure was the difference between these two values.

Postoperative. Physiological assessment of the gracilis neosphincter muscle was undertaken in all patients before, and at regular intervals during, electrical stimulation by placing the microballoon in the (neo)anal canal at the site of maximum contraction. The following measurements were made:

1. *Pressure–frequency relationship.* Each neosphincter was stimulated at the supramaximal voltage and pulse width of 210 μs over a range of frequencies (2, 5, 10, 15, 20, 25 and 30 Hz). The pressure increment above the baseline at each frequency was recorded. The pressure generated was plotted against frequency of stimulation; this describes a sigmoid curve. To facilitate comparison between traces at different times, the frequency that generated 50 per cent of the maximum (fusion frequency) pressure was determined. This is termed the FF_{50}.
2. *Single twitch analysis.* The neosphincter was programmed to contract at 2 Hz continuously and the pressure was recorded. The time from the onset to the peak of each contraction (time to peak pressure) was recorded.
3. *Basal neosphincter pressure.* This was the pressure recorded at the site of the neosphincter when the stimulator was off.
4. *Maximum achieved neosphincter pressure.* This was the pressure recorded when the muscle was activated at tetany and supramaximal (or maximum tolerated) voltage.
5. *Maximum neosphincter squeeze pressure.* This was the difference between the basal neosphincter pressure and the maximum achieved pressure.
6. *Functioning neosphincter pressure.* This was the pressure generated at the site of the neosphincter after it had been activated continuously at 10 Hz. This was considered to be the patient's new functioning basal pressure or the 'sustainable' neosphincter pressure.

The functioning neosphincter pressure could be measured only in the 'relatively fatigued' state. It could not be determined during the electrical conditioning period or when the neosphincter was defunctioned by a temporary stoma. The neosphincter basal, maximum achieved and maximum squeeze pressures were measured after a rest period of 60 min.

Histochemical measurements

Biopsies were taken from the gracilis muscle at the various operative stages. Samples were removed at the first two operations when the whole muscle was exposed. Poststimulation biopsies were taken at the time of stoma closure under direct vision through a small incision placed about 5 cm from the anal canal. All biopsies were from the superficial aspect of the middle two quarters of the gracilis. In two patients a further biopsy was obtained after more than 16 months of low-frequency electrical stimulation during unrelated surgical procedures. Biopsies were orientated and snap-frozen in isopentane–liquid nitrogen. Sections 7 μm thick were cut and stained with myosin adenosine 5′-triphosphatase (ATPase) at various pH using a standard technique[14]. Under acid preincubation conditions, type 1 fibres stain darkly and type 2 fibres lightly; under alkaline conditions the reverse occurs. Type 2 fibres were not subdivided in this study.

The proportion of type 1 and 2 fibres was determined by counting at least 200 randomly selected fibres in each biopsy (a small number of biopsies contained fewer than 200 fibres, in which case all were counted). Fibre size was assessed by measuring the lesser diameter of 100 randomly selected fibres (of type 1 or 2) in each biopsy. To ensure a random selection of fibres, all those in a given microscope field were counted or measured. Fibres partly in one field and partly in another were not included. The slide was then moved 'blindly' to another part of the biopsy and all fibres in that field counted or measured. This process was continued until the required number of fibres had been assessed. To facilitate measurement the microscope was linked to a computerized analysis system (Magiscan; Joyce-Loebl, Gateshead, UK).

Statistical analysis and presentation of results

All results were expressed as median (95 per cent confidence interval). Comparisons between two groups were made using the Mann–Whitney *U* test for unpaired data or the Wilcoxon signed rank test for paired data. Comparisons involving more than two groups were made after preliminary analysis using the Kruskal–Wallis test for unrelated groups or the Friedman test for repeated observations on the same group of patients.

Results of measurements made on repeated occasions after neosphincter construction are expressed in various time epochs. Each patient is represented only once for a particular measurement in each epoch or not at all if no measurement was made during that period.

Results

Pressure–frequency relationship

The FF_{50} decreased significantly ($P < 0{\cdot}01$) after 31–90 days of low-frequency stimulation and remained decreased throughout the follow-up period (*Figure 1*).

In seven patients electrical stimulation was temporarily stopped for at least 4 weeks because of electrode plate displacement or perineal sepsis. The results of the FF_{50} before stopping electrical stimulation and after recommencement are shown in *Figure 2*. Between the initial assessment before starting stimulation and the last assessment before stopping stimulation the FF_{50} decreased in accordance with the overall results ($P = 0{\cdot}018$). At the first assessment after recommencement of stimulation the FF_{50} had reverted towards the original prestimulation value ($P = 0{\cdot}018$). Continued low-frequency electrical stimulation was associated with a further significant decrease in FF_{50} ($P = 0{\cdot}043$).

Stimulation of the gracilis neosphincter muscle at both 2 Hz continuously ($P < 0{\cdot}05$) and at 10–25 Hz intermittently ($P = 0{\cdot}004$) produced a significant decrease in FF_{50} (*Table 2*). There was no difference in the efficacy of the changes between the two frequency regimens.

Single twitches

The times to peak pressure of individual muscle twitches at various times after starting low-frequency electrical stimulation are shown in *Figure 3*. The time to peak pressure increased

Table 3 *Anal canal pressures before and after operation*

	Group 1 median (95% confidence interval) pressure (cmH$_2$O) ($n = 11$)	Group 2 median (range) pressure (cmH$_2$O) ($n = 8$)
Preoperative maximum basal pressure	42·8 (32·5–55·5)	15·0 (8·0–22·5)
Basal neosphincter pressure	37·8 (32·5–47·0)	30·2 (22·0–35·0)
Functioning neosphincter pressure	63·0 (51·0–77·5)	47·8 (30·0–68·5)
Preoperative maximum squeeze pressure	13·0 (7·5–19·5)	8·5 (1·0–17·0)
Maximum neosphincter squeeze pressure	57·5 (45·0–106·5)	57·2 (38·5–87·5)

Maximum basal *versus* basal neosphincter pressure: group 1, *P* not significant; group 2, $P < 0{\cdot}05$. Functioning neosphincter *versus* maximum basal pressure: groups 1 and 2, $P < 0{\cdot}05$. Functioning neosphincter *versus* basal neosphincter pressure: groups 1 and 2, $P < 0{\cdot}05$. Maximum neosphincter squeeze *versus* maximum squeeze pressure: group 1, $P = 0{\cdot}003$; group 2, $P < 0{\cdot}01$ (Wilcoxon signed rank test)

significantly after 21–40 days ($P = 0{\cdot}025$) and further after 41–60 days ($P = 0{\cdot}006$) of low-frequency stimulation. It then remained increased throughout the follow-up period.

Preoperative and postoperative anal canal pressure (Table 3)

The postoperative basal neosphincter pressure did not change significantly during the follow-up period. For patients in group 1, the basal neosphincter pressure (taken as the mean of the last three assessments) was not significantly different from the preoperative maximum basal pressure ($P = 0{\cdot}037$). However, the eventual functioning neosphincter pressure was significantly greater than both the preoperative maximum basal ($P < 0{\cdot}05$) and postoperative neosphincter basal ($P < 0{\cdot}05$) pressures.

For patients in group 2, the basal neosphincter pressure was significantly greater than the preoperative maximum basal pressure ($P < 0{\cdot}05$) and the eventual functioning pressure was greater than both the neosphincter basal ($P < 0{\cdot}05$) and maximum basal ($P < 0{\cdot}05$) pressures.

The maximum neosphincter squeeze pressure (*Figure 4*) decreased significantly over the first 180 days of electrical stimulation ($P = 0{\cdot}004$), although then appeared to recover partially. The value at 181–365 days was significantly greater than at 91–180 days ($P = 0{\cdot}016$), but was still lower than the 0–30-day value ($P = 0{\cdot}008$). The maximum neosphincter squeeze pressure, arbitrarily taken as the mean of the last three measurements, was significantly greater than the preoperative maximum squeeze pressure for patients in groups 1 ($P = 0{\cdot}003$) and 2 ($P < 0{\cdot}01$).

Histochemical results (Table 4)

Of the 49 biopsies taken, 20 were found to be inadequate for quantitative analysis because the sample contained no muscle (or inadequate muscle) or because of freeze artefacts. The proportion of inadequate biopsies between the three operative stages was not significantly different.

In the biopsies taken before vascular delay, there was no difference in the proportion of type 1 fibres between male and female patients, and no correlation with age. Fibre diameters were significantly greater in male compared with female patients ($P < 0{\cdot}05$), although there was no association between age and

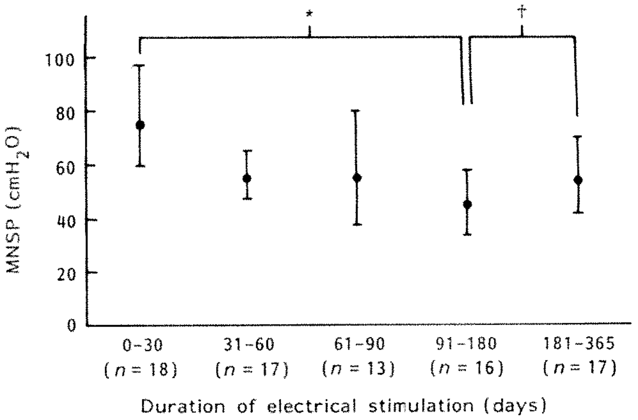

Figure 4 *Change in maximum neosphincter squeeze pressure (MNSP) with time. Values are median (95 per cent confidence interval).* P = *0·0063 (Friedman two-way ANOVA);* *P = *0·0043;* †P = *0·016 (Wilcoxon signed rank test)*

Table 4 *Histochemical results: percentage and diameter of type 1 and type 2 fibres*

	Stage 1 (before vascular delay; $n = 13$)	Stage 2 (after vascular delay, before stimulation; $n = 7$)	Stage 3 (after stimulation; $n = 7$)*
Percentage of type 1 fibres	34·0 (31·5–36·0)	30·0 (23·0–36·5)	67·2 (45·0–87·0)
Diameter of type 1 fibres (μm)	36·8 (32·2–45·9)	42·4 (33·5–45·9)	30·2 (25·5–32·8)
Diameter of type 2 fibres (μm)	32·8 (25·5–39·9)	35·5 (25·5–47·0)	27·8 (15·8–38·9)

Values are median (95 per cent confidence interval). *At time of stoma closure (median duration 80 (range 49–137) days after transposition). No significant differences were found between stages 1 and 2, or between any stage for type 2 diameter. Percentage of type 1 fibres: stage 1 *versus* stage 3: $P = 0{\cdot}004$; stage 2 *versus* stage 3: $P = 0{\cdot}002$. Diameter of type 1 fibres: stage 1 *versus* stage 3: $P = 0{\cdot}02$; stage 2 *versus* stage 3: $P < 0{\cdot}02$ (Mann–Whitney *U* test) fibre diameter in this group. In all biopsies from female (but not male) patients, type 1 fibres were larger than those of type 2 ($P < 0.01$). There was no significant difference in the percentage of type 1 fibres nor in their diameter after the preliminary vascular delay procedure.

Gracilis muscle transposition and low-frequency electrical stimulation (mean duration 80 (range 49–137) days) was associated with a significant increase in the proportion of type 1 fibres (*Table 4*). The diameter of such fibres after electrical stimulation was significantly less than that before transposition and stimulation.

Two late biopsies taken 16 and 21 months after starting low-frequency electrical stimulation showed an increase in the proportion of type 1 fibres compared with earlier samples from the same patients (61 and 98 per cent type 1 fibres for one patient, 45 and 81 per cent for the second). The fibre diameters did not appear to change markedly between the early and late poststimulation biopsies.

Discussion

Electrical stimulation of the gracilis neosphincter may provide additional benefit compared with the conventional gracilis sling operation for two reasons. First, the stimulator gives the neosphincter properties of active contraction and passive relaxation that may be voluntarily controlled by the patient using a small magnet placed over the device. Second, electrical stimulation may convert fast-twitch muscle to that of slow-twitch type, giving the muscle the additional useful property of fatigue resistance. The results of the present study confirm the ability of electrical stimulation to produce this transformation in human muscle.

There was a significant decrease in FF_{50} after 21 or more days of low-frequency electrical stimulation. This means that twitch summation and tetanic fusion are occurring at a lower frequency. Similarly, the time to peak pressure increased after stimulation. These changes are indicative of transformation from fast to slow muscle[15].

In isolation, these physiological changes cannot be considered proof of muscle fibre type conversion. Other changes such as muscular or perimuscular fibrosis or an adaptation to a change in muscle length[16] after transposition could produce similar results. However, the histochemical studies indicate that transposition and electrical stimulation results in a significant increase in the proportion of type 1 fatigue-resistant fibres. The myosin ATPase technique is the standard method to assess muscle fibre type[14]. It is interesting that the two late biopsies showed a further increase in the proportion of type 1 fibres, suggesting that in these patients transformation was incomplete at the time of stoma closure and continued afterwards. However, the physiological changes were apparent after only 21 days of low-frequency stimulation.

The reversibility of changes in FF_{50} (*Figure 2*) is additional evidence that the physiological effects result from muscle fibre type conversion. If the changes were caused by fibrosis or a change in muscle length, they would be unlikely to be reversible. Furthermore, in each of the seven patients in whom electrical stimulation was temporarily stopped, the degree of continence deteriorated during the period of no stimulation compared with that of continuous stimulation. These observations emphasize the need for continued stimulation.

Both patterns of low-frequency electrical stimulation used produced changes consistent with conversion from fast- to slow-twitch muscle. This supports the generally held view that it is the increase in overall (or aggregate) neuronal activity that is responsible for changes in the characteristics of skeletal muscle[7,17]. No difference in the efficacy of muscle transformation was noted between the two patterns, although further studies are required to compare different stimulation regimens.

The maximum pressure that the neosphincter could generate decreased significantly over the first 6 months of electrical stimulation, then underwent a partial but significant recovery (*Figure 4*). The diameter of type 1 fibres decreased significantly following transposition and stimulation. The diameter of type 2 fibres also decreased although the change was not statistically significant, perhaps because there were relatively few type 2 fibres available for measurement in many of the poststimulation samples.

A reduction in fibre diameter may be an inevitable consequence of electrical stimulation. The mean fibre diameter of the rabbit tibialis anterior muscle decreased by 25 per cent after 4–6 weeks of low-frequency stimulation *in situ*[7]. It has been suggested that decrease in fibre size may be a factor in enhancing fatigue resistance by reducing the diffusion distance between capillaries and the centre of fibres[18]. A much more profound reduction in muscle strength has been observed with latissimus dorsi cardiomyoplasty[19], in which the latissimus dorsi muscle is transposed into the thorax, wrapped around the heart and stimulated electrically to augment or replace ventricular function. Salmons and Jarvis[20] reported an 80 per cent reduction in acute power output of the latissimus dorsi muscle following this procedure. This may be because, in cardiomyoplasty, the latissimus dorsi is not resutured to bone after transposition. In the gracilis neosphincter procedure the muscle is fixed to the ischial tuberosity. This may maintain sufficient stretch to reduce the degree of muscle atrophy.

The reduction with time in pressure-generating capacity of the gracilis neosphincter may eventually compromise function; future research should be directed at limiting this problem. There is recent evidence that patterns incorporating a 'background' of low-frequency stimulation plus intermittent very short bursts of high-frequency stimulation (100 Hz) may result in transformation into a slow-twitch fatigue-resistant muscle but with preservation of muscle mass[19,21]. Alternatively, optimizing the degree of muscle stretch during neosphincter construction may minimize muscle atrophy. Goldspink *et al.*[22] demonstrated that electrical stimulation of an understretched muscle results in atrophy, whereas stimulation of a stretched muscle may increase its mass.

The observed significant recovery in the maximum neosphincter squeeze pressure in the present study between 6 and 12 months is intriguing and may represent continued adaptation by the gracilis muscle to its new location or function. Further studies are needed to confirm this partial recovery and to investigate its underlying cause.

The basal neosphincter pressure was not found to be significantly different from the preoperative maximum basal pressure for patients with faecal incontinence. This may help to explain the generally poor results of the conventional gracilis sling operation performed without stimulation[6]. In contrast, the sustainable pressure generated by the neosphincter was significantly greater than both the maximum basal and basal neosphincter pressures, confirming the utility of prolonged stimulation.

In summary, this study has demonstrated that the human gracilis muscle is capable of physiological and histochemical adaptation to long-term neosphincter function. The reversibility of the physiological changes emphasizes the importance of continued electrical stimulation.

A selection from the September issue of the American journal.

Reduction of systemic drug exposure after hepatic arterial infusion of doxorubicin with complete hepatic venous isolation and extracorporeal chemofiltration

Steven A. Curley, MD, David R. Byrd, MD, Robert A. Newman, PhD, Harvey J. Ellis, CCP, Judy Chase, PharmD, Cesar H. Carrasco, MD, Karen Cleary, MD, William Bodden, MD, *and* **David C. Hohn, MD,** *Houston, Texas, Bridgeport, Conn., and New York, N.Y.*

Background. *Hepatic arterial infusion of doxorubicin has produced tumor response in hepatic malignancies; however, the limited success of these treatments is related in part to dose-limiting systemic toxicities. The purpose of this study was to determine whether a novel venous isolation–chemofiltration system could limit systemic exposure to doxorubicin after hepatic arterial infusion.*
Methods. *Doxorubicin (1 or 3 mg/kg) was infused in the hepatic arteries of domestic pigs after complete hepatic venous isolation was achieved with a dual-balloon vena cava catheter. The hepatic vein effluent was pumped through an extracorporeal carbon chemofiltration circuit. Doxorubicin levels were measured in prefilter (hepatic vein), postfilter, and systemic serum at intervals up to 1 hour after drug infusion.*
Results. *Complete hepatic venous isolation with extracorporeal chemofiltration significantly reduced (>90%) the postfilter and systemic levels of doxorubicin compared with prefilter levels ($p < 0.01$). At the time animals were killed 7 days after infusion of doxorubicin (3 mg/kg), tissue levels of doxorubicin in the liver showed a 16-fold increase compared with levels in the heart ($p < 0.01$).*
Conclusions. *For chemotherapeutic drugs like doxorubicin with a low first-pass extraction by the liver, the novel system described herein achieved significant reduction in systemic drug exposure. This system will allow dose intensification of doxorubicin administered by hepatic arterial infusion to treat hepatic malignancies. (*SURGERY *1993;114:579-85.)*

Interleukin-6 mediates host defense responses induced by abdominal surgery

Cornelis H. Wortel, MD, Sander J. H. van Deventer, MD, Lucien A. Aarden, PhD, Nicolas J. Lygidakis, MD, Harry R. Büller, MD, Frans J. Hoek, PhD, Jos Horikx, BA, *and* **Jan W. ten Cate, MD,** *Amsterdam, The Netherlands*

Background. *Cytokines have been implicated as pivotal mediators of the host defense reaction. In patients undergoing surgery we investigated the relationship between such mediators and postoperative host defense responses.*
Methods. *Tumor necrosis factor (TNF) was determined with an immunoradiometric assay, interleukin (IL)-6 by a B9-cell bioassay, and endotoxin by a chromogenic* Limulus *lysate assay. C-reactive protein, α_1-antitrypsin, and α_2-macroglobulin were quantified by nephelometric assay.*
Results. *In 19 consecutive patients undergoing pancreaticoduodenectomy, a large increase in portal, and a significantly lower increase in peripheral, IL-6 levels was observed. No significant increase in TNF levels was noted. Fever developed in 16 patients within 24 hours (84%). The highest peripheral IL-6 levels correlated logarithmically ($R = 0.59$; $p = 0.0039$) with the peak body temperatures. C-reactive protein levels correlated with IL-6 levels ($R = 0.49$; $p = 0.020$). Increased IL-6 levels were observed in all nine patients undergoing either hemihepatectomy, breast reduction, or extensive breast reconstruction; however, only patients undergoing hemihepatectomy had endotoxemia.*
Conclusions. *We conclude that abdominal surgery causes acute release of IL-6, but not TNF, in the portal circulation. IL-6 seems to be a major endogenous mediator of fever and the acute-phase response. The presence of endotoxin might be synergistic but is not obligatory for the host defense response after surgical trauma. (*SURGERY *1993;114:564-70.)*

The effect of acute nonbacterial dependent peritonitis on lung and liver oxidant stress and antioxidant activity

Robert Demling, MD, Ramona Daryani, BS, Cara Campbell, BS, James Knox, MD, Yeo-Kyu Youn, MD, *and* **Cheryl Lalonde, BS,** *Boston, Mass.*

Background. *The role of oxidant release and tissue antioxidant defenses on inflammation-induced organ injury is not clearly defined.*
Methods. *We determined the effect of acute zymosan peritonitis in rats on lung and liver tissue oxidant stress and antioxidant defenses during a 5-day period. Oxidant activity was measured as tissue malondialdehyde and oxidized glutathione (GSSG). Antioxidant activity was measured as tissue-reduced glutathione (GSH) and catalase activity. Rats were maintained hydrated with subcutaneous crystalloid. Animals were killed at 4, 12, and 24 hours and 5 days.*
Results. *Acute peritonitis was evident at 12 and 24 hours but was resolving at 5 days. Peritoneal fluid cultures were negative after 24 hours. A 50% mortality rate was noted between 20 and 30 hours, with no deaths after 30 hours. We noted a significant increase in lung GSSG and malondialdehyde at 4 hours that persisted for the 5 days, as did histologic evidence of a progressing severe lung inflammation. No increased conversion of lung xanthine dehydrogenase to xanthine oxidase was noted. Lung GSH and catalase activity were maintained at*

control despite negligible food intake. In contrast, liver GSSG was increased significantly only at the 4-hour period, corresponding with a transient conversion of xanthine dehydrogenase to xanthine oxidase from 10% to 31%. Tissue malondialdehyde did not increase despite the initial oxidant stress. However, tissue GSH and catalase values decreased by more than 50% after 24 hours and remained decreased at 5 days.

Conclusions. *We conclude that early lung and liver oxidant stress is initiated by acute peritonitis. Lung oxidant changes persist and lung dysfunction progresses, even though antioxidant activity is maintained and acute peritonitis is resolving. Liver lipid peroxidation did not develop despite oxidant release, probably because of a large antioxidant reserve. However, a severe and sustained decrease in liver antioxidants results, increasing the potential damage from a subsequent oxidant insult. (SURGERY 1993;114:571-8.)*

The effect of erythromycin on motility of the duodenum, sphincter of Oddi, and gallbladder in the prairie dog

Howard S. Kaufman, MD, Steven A. Ahrendt, MD, Henry A. Pitt, MD, *and* **Keith D. Lillemoe, MD,** *Baltimore, Md.*

Background. *Interdigestive motility of the stomach, duodenum, sphincter of Oddi, and gallbladder is mediated through the migrating myoelectric complex and the action of motilin. Erythromycin, a motilin agonist, has recently been studied as a gastrointestinal and biliary prokinetic agent. We hypothesized that erythromycin would increase interdigestive duodenal and sphincter of Oddi motility in a dose-dependent manner.*

Methods. *In 10 anesthetized prairie dogs we determined the motility responses of the duodenum, sphincter of Oddi, and gallbladder to erythromycin infusion during a three-log dosing regimen and correlated activity with serum concentrations of the drug.*

Results. *Erythromycin administered at 0.01 and 0.1 mg/kg had no effect on duodenal or sphincter motility. At 1.0 and 10 mg/kg, duodenal motility index increased by 451% ± 114% and 1070% ± 480%, respectively, when compared with baseline values ($p < 0.05$). Sphincter of Oddi motility index increased by 122% ± 38% and 323% ± 99%, respectively, at these same doses of erythromycin ($p < 0.05$). Gallbladder pressure did not change significantly during erythromycin infusion. Erythromycin serum concentration at 1.0 mg/kg was 1.0 ± 0.7 μg/ml.*

Conclusions. *These data suggest that erythromycin stimulates interdigestive motility of the duodenum and sphincter of Oddi in a dose-dependent manner at otherwise subtherapeutic concentrations of the drug. (SURGERY 1993;114:543-8.)*

Safe intraabdominal pressure of carbon dioxide pneumoperitoneum during laparoscopic surgery

Yoichi Ishizaki, MD, Yasutsugu Bandai, MD, Kazuyuki Shimomura, MD, Hideki Abe, MD, Yumiko Ohtomo, MD, *and* **Yasuo Idezuki, MD,** *Tokyo, Japan*

Background. *The deliberate induction of carbon dioxide pneumoperitoneum during laparoscopic surgery could be a possible source of cardiovascular collapse. The effects of elevated intraabdominal pressure (IAP) on systemic hemodynamics and splanchnic blood flow created by insufflation of carbon dioxide were examined in anesthetized dogs.*

Methods. *Stepwise increases in IAP of 8 ($n = 7$), 12 ($n = 7$), and 16 ($n = 7$) mm Hg were applied to determine the threshold pressure that had minimum influence on these hemodynamics. Hemodynamic parameters were measured at baseline and 1, 2, and 3 hours after the start of insufflation.*

Results. *At an IAP of 16 mm Hg, cardiac output was decreased significantly by 1 hour after the start of insufflation and became progressively lower during the procedure. Systemic vascular resistance was elevated significantly in parallel with the change in cardiac output. Although hepatic arterial blood flow was not decreased significantly, portal venous and superior mesenteric arterial blood flows were diminished significantly at 16 mm Hg, resulting in a decrease in total hepatic blood flow. No significant changes were observed in these parameters at 8 or 12 mm Hg.*

Conclusions. *Based on these results, an IAP from 8 to 12 mm Hg is recommended for laparoscopic surgery, to avoid complications caused by hemodynamic derangements. (SURGERY 1993;114:549-54.)*

Growth-related gene expression in early cholestatic liver injury

Thomas F. Tracy, Jr., MD, Mary E. Goerke, BA, Patrick V. Bailey, MD, Cirilo Sotelo-Avila, MD, *and* **Thomas R. Weber, MD,** *St. Louis, Mo.*

Background. *Extrahepatic biliary obstruction initiates cholestasis, bile duct proliferation, periportal fibrosis, and, eventually, lethal biliary cirrhosis. Little is known about the genetic regulation of the cellular proliferation and differentiation that begins with the onset of bile duct obstruction. To focus this and future gene expression studies, we sought to determine the time frame for growth-related gene expression and questioned whether the in vivo expression of the protooncogenes H-ras and c-myc was altered after bile duct obstruction.*

Methods. *Female Fisher rats underwent ligation and division of the common bile duct or sham laparotomy.*

Results. *After obstruction, serum bilirubin and γ-glutamyl transpeptidase rose to 24% and 30%, respectively, of maximum levels by 10 days after ligation. Morphologic evidence of proliferation of bile duct epithelial cells was first evident after 3 days. After hybridization to c-DNA probes, densitometry for H-ras and β-actin revealed an immediate and parallel increase in steady-state levels of expression after 24 hours of cholestasis. Levels of c-myc messenger RNA were elevated during the first 3 days of cholestasis; however, at 7 and 10 days c-myc expression was depressed 16% and 60%, respectively.*

Conclusions. *These profiles of expression show an oncogene response induced by early cholestasis. These data showed that elevations in H-ras and c-myc steady-state expression accompany the proliferative response of bile duct epithelial cells. Decreased levels of c-myc after initial elevation infer that ductal proliferation may continue independently of its steady-state expression, a response usually seen in vitro rather than in vivo proliferation. (SURGERY 1993;114:532-7.)*

Correspondence

Herniation at the site of cannula insertion after laparoscopic cholecystectomy

Letter 1

Sir

We read with interest the recent Case Report by Messrs McMillan and Watt (*Br J Surg* 1993; **80**: 915). We have previously reported the complication of small bowel herniation through the umbilical wound from a 10-mm port, resulting in obstruction that required small bowel resection[1]. In this case the gallbladder had also been removed through the epigastric cannula, suggesting that a wound of 10 mm is sufficient for this problem to arise. We believe that the complication has not been encountered following gynaecological laparoscopy as nearly all procedures use 5- or 8-mm cannulas. We had attempted closure of the defect with a 2/0 polyglactin suture, and feel this illustrates the difficulties encountered in closure of the fascial layer through such a small incision. We have found the use of a J shaped needle facilitates closure of the wound. The report of small bowel obstruction secondary to suturing of the small bowel to the abdominal wall demonstrates the need for adequate exposure for the placement of sutures under direct vision[2]. Although the wounds are small and some believe closure to be unnecessary, further reports of this nature may help settle the debate of whether to close fascial defects after laparoscopic surgery.

Letter 2

Sir

I read with interest the Case Report by Messrs McMillan and Watt (*Br J Surg* 1993; **80**: 915) describing herniation at the site of cannula insertion after laparoscopic cholecystectomy. The authors state that theirs is the first report of intestinal obstruction secondary to bowel entrapment at the site of an incision used for a 10-mm laparoscopic cholecystectomy port. In fact a very similar case was reported by Boyce and colleagues[2] in July 1992. They described a patient developing small bowel obstruction in the immediate postoperative period caused by entrapment of a loop of small bowel at the fascial defect occurring at the site of insertion of the umbilical cannula. A further case of the same complication was described in the series of Martin and colleagues[2] in August 1992.

In a personal series of 133 laparoscopic cholecystectomies (54 as cameraman, 25 as operator under supervision, 54 as principal operator) I encountered the same complication in patient 6 in this group. She presented 6 weeks after operation with a lump at the site used for the epigastric cannula. At operation a small hernia containing small bowel was found and repaired. It is of interest that in this patient the fascia had not been sutured. Having subsequently read reports of this complication, the fascial defect at the site of the epigastric and umbilical cannula sites has been repaired using no. 1 polydioxanone on a J needle in all patients. There have been no further hernias. Although this is a rare complication, it seems reasonable practice to repair a defect of $\geqslant 10$ mm in size in the anterior abdominal wall. Anxiety regarding the possibility of picking up a loop of small bowel during closure of the fascial defect can be minimized by leaving the camera in place to inspect the underside of the epigastric wound after repair.

Finally, all four cases describe hernias at the site of 10-mm cannulas. Herniation at the smaller 5-mm cannula sites is less likely because of the smaller defect and, possibly, because these cannulas are inserted more obliquely so that the skin puncture site may be 2–3 mm from the point of entry into the peritoneal cavity.

Laparoscopic abdominoperineal resection of the rectum

Sir

I read with interest the comments of Dr Rehman (*Br J Surg* 1993; **80**: 1080) regarding my article (*Br J Surg* 1992; **79**: 1207–8). I fully agree that for abdominoperineal resection for carcinoma the inferior mesenteric artery must be ligated high and early, and would point out that the first case that I reported was performed for benign disease. While I agree that the operation can be done with four ports, I do not think that one should 'gild the lily' by struggling. Although I would normally now use four ports for all colonic and rectal procedures, if I have any problems I put a fifth one in. I was intrigued by Dr Rehman's use of a plastic rod to manipulate the rectum – I have merely used a rigid sigmoidoscope to achieve this end. However, I do feel that the technique to create the colostomy reported by him runs the risk of contaminating the abdominal cavity. One of the problems with laparoscopic bowel surgery is ensuring that the abdomen remains clean. My technique of stapling the bowel closed prevents any chance of faecal spillage, which a purse string does not. As far as time taken to perform the operation is concerned, certainly with increasing experience it gets faster. I thank Dr Rehman for his useful technical tips; we must all continue to trade 'secrets' to ensure skills in this area are improved.

Conventional *versus* laparoscopic surgery for acute appendicitis

Sir

The recent paper by Mr Tate and colleagues (*Br J Surg* 1993; **80**: 761–4) raises a number of interesting questions about the role of laparoscopic appendicectomy. Our experience is very similar to that described (*Table 1*). Of the first 48 attempted laparoscopic appendicectomies, three were converted to open procedures, all within the first month of using this technique. In each case the appendix was gangrenous or perforated. We are now happy to deal with an appendix that is inflamed right down to the caecum, using intracorporeal suturing of the base where necessary. Surgeons genuinely experienced in laparoscopic cholecystectomy, especially in patients with acute cholecystitis, should have a rapid 'learning curve' for laparoscopic appendicectomy. Our mean operating time for completed cases was 52 (range 20–105) min; this includes time from induction of anaesthesia to dressing the incisions. Compared with a group of patients matched for age, sex and severity of appendicitis who underwent conventional

Table 1 *Laparoscopic* versus *conventional appendicectomy*

	Laparoscopic ($n = 45$)	Conventional ($n = 45$)
Doses of intramuscular analgesia*	3 (0–9)	3 (0–8)
Hospital stay (days)*	4	4
Wound infection	0	1
Pelvic or abdominal abscess	0	0

*Values are median (range)

appendicectomy, the laparoscopic approach conferred no advantage in terms of postoperative analgesia requirement or length of hospital stay. There were no wound infections in the laparoscopic group, although there was one port haematoma. None of the patients developed an intra-abdominal abscess.

The operation does not therefore appear to carry the advantages that have been well documented for the laparoscopic approach to cholecystectomy or Nissen fundoplication. We doubt the value of randomized trials comparing laparoscopic with conventional appendicectomy.

Attention in further studies need to be directed towards return to normal activities in the period after discharge and whether patients find three laparoscopic scars more acceptable than the usual wound in the right iliac fossa.

Contemporary management of the appendiceal mass

Sir

I take issue with the comments of Messrs Sargeant and Mason, and Mr Ridings concerning the management of appendiceal mass (*Br J Surg* 1993; **80**: 810).

Sargeant and Mason regard as 'speculative' the fact that 80 per cent of patients recovering from an appendiceal mass will not require subsequent appendicectomy. This figure is, however, based on well documented studies[1]: of a total of 207 patients followed for between 6 months and 22 years without interval appendicectomy, only 22 (10·6 per cent; range 0–20 per cent) suffered recurrent appendicitis. I agree that those travelling to remote locations should be offered elective appendicectomy and have previously stated this advice[1]. Sargeant and Mason also claim that delay in diagnosis of caecal tumours will result if interval appendicectomy is omitted. This pitfall can be obviated if all patients with an appendiceal mass subsequently undergo barium studies or colonoscopy.

Mr Ridings' argument that percutaneous abscess drainage is not always available is correct, but most patients can be managed entirely conservatively, with neither percutaneous nor operative drainage but with successful outcome[2] within 10 days. His lucky experience with immediate appendicectomy in five cases contrasts with the warnings of others that immediate appendicectomy is fraught with complications and the danger of misdiagnosing the appendiceal pathology[1,2].

Single-loop biliary and gastric bypass for irresectable pancreatic carcinoma

Sir

We read with interest the paper by Dr Watanapa and Professor Williamson (*Br J Surg* 1993; **80**: 237–9) about a biliary and gastric bypass with a single retrocolic Roux loop. We appreciate the need for a simple and effective palliative procedure in irresectable pancreatic cancer, but with our experience in 51 patients favour a single-loop biliary and gastric bypass even without enteroanastomosis.

This technique was introduced by Dr R. Hermann[1]. The first loop of the jejunum is used for an antecolic isoperistaltic side-to-side gastrojejunostomy to the gastric antrum (two-layer or stapled anastomosis 7·5 cm in length) and 10–15 cm distally for a biliary end-to-side anastomosis to the fundus of the gallbladder (one-layer or stapled anastomosis 5·0 cm in length). In the presence of gallstones, after previous cholecystectomy or in cases of cystic duct junction close to the tumour, anastomosis to the common hepatic duct is performed.

Since 1986 we have carried out this procedure on 28 female and 23 male patients with a median age of 67 (range 44–82) years. The median operating time was 2·0 (range 1·0–3·0) h, markedly shorter than in Watanapa's patients (4·0 (2·5–6·0) h), but we certainly agree that the operating time is influenced by the exploration of resectability. Minor postoperative complications occurred in ten patients and seven died within 30 days. Two patients suffered from cholangitis, a further two developed delayed gastric emptying despite a patent gastroenterostomy, and peptic ulcer complications required treatment with H_2-blockers in four patients. Serum bilirubin levels showed an adequate decrease in 48 patients. The median hospital stay after operation was 18 (range 9–40) days and median postoperative survival 5 (range 0–13) months.

Concerning the discussion about cholecystojejunostomy or choledochojejunostomy[2,3], we prefer primarily the use of the gallbladder as the technically simplest procedure in these patients with limited life expectancy. Our functional results in 43 patients are as good as for hepaticojejunostomy, which was necessary in eight patients.

Authors' reply

Sir

We thank Dr Lindemann and his colleagues for their letter. The point at issue is whether to use the gallbladder or common hepatic duct for anastomosis to the jejunum during bypass surgery for irresectable cancer of the pancreatic head. If the bile duct is chosen it may be technically simpler to use a Roux loop rather than jejunum in continuity, even though this necessitates an additional anastomosis.

Our own preference for cholecystectomy and choledochojejunostomy is based on personal observation. A substantial experience of pancreatoduodenectomy for chronic pancreatitis has underlined the frequency with which the cystic duct joins the common hepatic duct low down, i.e. close to the duodenum. Often the ducts appear to join at a higher level, but this proves to be an adventitial fusion and not the true luminal junction. Thus, if the cystic duct is to be used as a conduit for biliary bypass we regard on-table cholecystography as essential. Dr Lindemann does not report the incidence of early recurrent jaundice in his large series of cholecystojejunostomies, but we have had to reoperate on three such patients. One case was particularly instructive.

A 68-year-old woman underwent laparotomy for an apparently favourable carcinoma of the pancreatic head, but resection was abandoned because the tumour was fixed posteriorly. At this stage the systolic blood pressure fell to 40 mmHg and remained unresponsive to pressor drugs (including intracardiac adrenaline). Myocardial infarction was suspected, and we were encouraged by the anaesthetist to terminate the operation as soon as possible. A rapid cholecystojejunostomy was therefore carried out instead of the standard Roux loop bypass to stomach and bile duct that was described in our paper. During abdominal closure the patient's blood pressure improved spontaneously and she made a completely uneventful recovery; she received subsequent radiotherapy. Some 4 months later the woman became jaundiced again. Imaging revealed an obstructed cystic duct but no evidence of distant disease. At a second laparotomy the tumour was still irresectable. The gallbladder was removed and a single Roux loop was brought up for separate bile duct and gastric anastomoses. She remained in good health for several months, dying quickly from carcinomatosis 13 months after the original operation. It is ironic that her length of survival was greater than that of any of the other 25 patients reported in our paper.

Our policy is therefore to try to separate patients with carcinoma of the head of pancreas into two groups at the time of admission. Those who are unsuitable for operation by reason of extreme age, intercurrent disease or advanced cancer are treated with an expandable metal biliary stent. The younger fitter patients without extensive metastases are submitted to operation after imaging studies that include endoscopic retrograde cholangiopancreatography, computed tomography and (usually) visceral angiography. Resectable tumours are excised, and the other patients receive single-loop biliary and gastric bypass. With this protocol there is little or no indication for cholecystojejunostomy: those with a very limited prognosis should already have been identified and treated by stenting.

Endoscopic sympathectomy

Sir

Mr Hederman's timely Leading Article on thoracoscopic sympathectomy (*Br J Surg* 1993; **80**: 687–8) correctly stresses the superiority of this method over conventional cervical sympathectomy. In our experience of 95 sympathectomies in 49 patients, all those with hyperhidrosis were pleased with the initial results. However, we are concerned that, although perioperative and postoperative complications are uncommon, they may have disastrous consequences if their management is suboptimal.

Three of our patients developed appreciable and sustained hypoxia during the procedure, this phenomenon having also been noted by others[1]. In these cases it may be advisable to limit the procedure and carry out the second sympathectomy at a later date. We are currently studying the use of continuous high-frequency jet ventilation of both lungs in an attempt to reduce the incidence and degree of hypoxia. Pneumothorax requiring an underwater seal drain is a relatively frequent complication, occurring in 16 of our 49 patients, and may be serious *if not recognized early*. We recommend that all patients have chest radiography immediately after operation.

The risk of these complications should not be underestimated, especially when one considers that most procedures are performed on otherwise healthy young patients for cosmetic and social indications. Because of these potential problems, we believe that proficiency in laparoscopic surgery alone is not sufficient, and that surgeons and anaesthetists involved in these procedures should have had adequate training in thoracic surgery and anaesthesia.

Prospective randomized study of one- or two-layer anastomosis following oesophageal resection and cervical oesophagogastrostomy

Sir

I was very interested in the paper by Dr Zieren and colleagues (*Br J Surg* 1993; **80**: 608–11) on cervical oesophagogastrostomy. Having had experience of this technique since I first performed it in 1960, I would like to make the following comments, which are somewhat at variance with those made by my colleagues.

First, anastomosis in the neck results (in my experience) in fewer leaks than that in the chest, probably because of the ease of anastomosis in the superficial layer in the neck. Second, leaks in the chest are in my experience almost always fatal, whereas those in the neck are not. Third, regarding the type of anastomosis, I favour that with interrupted vertical mattress sutures using 3/0 ivory Mersilene (Ethicon, Edinburgh, UK) with the sutures spaced at intervals of 3 mm and the knots tied on the lumen. This suture line is supported by a continuous catgut suture involving only the outer layers of the anastomosis[1]. This type of anastomosis is very different from the two-layer construction shown in *Figure 1a* of their paper and is somewhat similar to that illustrated in *Figure 1b*, except that the knots are tied on the lumen and not on the outside. The second layer in the type of anastomosis that I recommend is a continuous catgut layer involving only the outermost layers of the oesophagus. Finally, I think that stricture following anastomosis can be avoided by employing two features: the oesophagus should be sectioned obliquely to increase the length of the stoma and the opening in the stomach should be crescentic[2].

My own conclusion after 30 years of experience in this field is that total oesophageal replacement with cervical anastomosis is a safer and better procedure than the two-phase technique.

Laparoscopic mobilization and exteriorization for minimally invasive small bowel resection

Sir

I read with interest the Surgical Workshop by Mr Attwood and colleagues (*Br J Surg* 1993; **80**: 225). Using this technique, I resected a leiomyoma of the small intestine that had caused recurrent episodes of heavy gastrointestinal bleeding before a diagnosis was made using an isotope scan. I agree with Mr Attwood and colleagues that, at least with the instruments currently available, extracorporeal resection and anastomosis is far superior to intracorporeal methods. Going a step further, I would propose this technique as the method of choice when dealing with large bowel obstruction.

The presence of distended large bowel makes intracorporeal handling, decompression, mobilization and resection very difficult. A 4–5-cm transverse incision is made at a point where a possible colostomy stoma may be sited. A segment of distended colon is delivered using atraumatic graspers, and through a purse-string suture the colon is decompressed using suction. This segment will then act as a plug to stop carbon dioxide leakage, while pneumoperitoneum is established using a cannula inserted through the same incision and accessory trocars are inserted. Mobilization of the colon is carried out to the required extent, and the mobilized segment is pulled out and resected. Thereafter the surgeon may choose to establish a colostomy or perform primary anastomosis extracorporeally.

This technique has many advantages that make it worth considering. Extracorporeal decompression allows better laparoscopic assessment and prevents intraperitoneal spillage of bowel contents. Pneumoperitoneum is established through a cannula placed next to the exteriorized segment after decompression, thus removing the risk of bowel injury. Traction on the exteriorized segment facilitates laparoscopic mobilization as it places peritoneal attachments and the mesocolon under tension. Finally, when this technique is used to establish a colostomy, second-stage surgery may be easier and can be performed sooner than after conventional procedures.

'Car-crusher colon'

Sir
Mr Whiteley and colleagues (*Br J Surg* 1993; **80**: 640) state that 'degloving' of the colonic outer wall has not previously been reported. Not so, for two reports exist in which such circumferential split-thickness transection of the intestinal wall occurred in vehicular accidents and was reported as seromuscular rupture[1,2]. The injury results from shearing forces induced by rapid deceleration, whereby the seatbelt strikes the intestinal wall.

Randomized trial comparing three forms of pelvic floor repair for neuropathic faecal incontinence

Sir
Professor Keighley's group reported (*Br J Surg* 1993; **80**: 794–8) an interesting trial that compared anterior sphincter plication alone, postanal repair and the two operations combined (total pelvic floor repair), and found that the combined operation is better.

Sultan *et al.*[1] demonstrated new sphincter defects in more than one-third of women following their first vaginal delivery. Furthermore, even when there is no clinical suspicion of sphincter injury, 36 per cent of patients with electrophysiologically confirmed pudendal neuropathy may have a sphincter defect demonstrated using anal endosonography[2].

Thus, in the absence of anal endosonography, there will be some women with a pure pudendal neuropathy and others with a combined sphincter injury and neuropathy despite the authors' attempts to exclude such patients. It is hardly surprising that these patients do better when their anterior sphincter injury is also attended to by anterior sphincter plication. Perhaps it is because of this that the trial found for total pelvic floor repair. What is not clear from the published data is whether, *given normal findings on anal endosonography*, anterior sphincter plication adds anything to postanal repair.

1. Sultan AH, Kamm MA, Hudson CH, Bartram CI. Vaginal delivery causes anal sphincter disruption in 37% of patients (prospective ultrasound study): a major determinant for development of faecal incontinence. *Gastroenterology* 1992; **102**: A522 (Abstract).
2. Law PJ, Kamm MA, Bartram CI. Anal endosonography in the investigation of faecal incontinence. *Br J Surg* 1991; **78**: 312–14.

Authors' reply

Sir
In response to the letter by Messrs Loder and Phillips, we confirm that routine anal ultrasonography was not available when all patients were being admitted to the pelvic floor repair trial, hence the suggestion that some of them might have had a clinically undetected anterior external sphincter injury is a possibility. Nevertheless, 3-year experience with anal ultrasonography on these groups of patients subsequent to the trial has led us to conclude that our clinical impression of complete sphincter division is accurate. We do accept that partial weakness of the external sphincter may be undetected clinically. Since it has always been our policy to perform an overlapping sphincter repair if there is an actual break in the external sphincter, such patients would never have been admitted to the trial in any case. We acknowledge that some weakness of the external anal sphincter anteriorly is very common in postobstetric neuropathic faecal incontinence. It is this observation, together with the results of our randomized trial, that leave us in no doubt that total pelvic floor repair is a more logical and successful operation than postanal repair alone.

Anal endosonography and correlation with *in vitro* and *in vivo* anatomy

Sir
We enjoyed reading the recent article by Mr Sultan and colleagues (*Br J Surg* 1993; **80**: 508–11), which rectified their earlier observation on the endosonographic anatomy of the anal canal[1]. We would like to call attention to the fact that the basic endosonographic appearance of the internal and external anal sphincters using *in vitro* and *in vivo* techniques had previously been reported by us 2 years ago[2,3], even though we did not identify the longitudinal muscle they described.

Regional anaesthesia and surgical morbidity

Sir

The question of whether regional anaesthesia in appropriate patients is superior to general anaesthesia has been discussed for many years. In the past decade, at least two well conducted randomized trials of sufficient sample size[1,2] showed that for mortality no benefit is given by regional anaesthesia. Nevertheless, Messrs Scott and Kehlet (*Br J Surg* 1988; **75**: 299–304) claim that 'the large amount of data suggests that (regional anaesthesia) should be used ... whenever possible'. They state, based on their meta-analysis[3], a '30 per cent reduction in early mortality'. If their conclusion were correct, regional anaesthesia would indeed have to be advocated in all appropriate cases.

Unfortunately, Scott and Kehlet give no evidence that it is justified to pool the mortality rates given in the cited papers (*Figure 1* of the publication). No test for homogeneity or heterogeneity was performed. The legend of *Figure 1* suggests that in all cited studies mortality was counted until the 30th day after operation. Unfortunately, this is not the case. The authors give the mortality rate for one cited study[4] until the 14th day, regardless of the fact that, in this study, the mortality is given for each day until the 56th. Regarding another study[5], it was overlooked that five deaths were excluded from comparison because of reinterventions and that the mortality rates cited reflect the first 3 months after operation. A further study[1] gives mortality until the 28th day, not the 30th.

Some of the papers in their meta-analysis included both sexes, others only women. Regional anaesthesia was spinal in one study and epidural in another, and the methods of general anaesthesia used covered the whole spectrum from methoxyflurane to neuroleptanalgesia, from spontaneous breathing by a face mask to controlled ventilation in intubated patients, and nearly all available muscle relaxants. Finally, one study[6] was not randomized, and the sizes of the trials analysed range from 40 to 578 patients.

I wonder whether meta-analysis can be carried out in this way and doubt, until better evidence is given, that 'the large amount of data suggests that (regional anaesthesia) should be used ... whenever possible'. Is it justified to pool mortality rates covering very different postoperative timespans from studies with very dissimilar sample sizes, then to calculate a significant difference ($P < 0{\cdot}01$) and to make such a statement?

Authors' reply

Sir

In our paper we reviewed data from controlled trials at that time and emphasized that a proper meta-analysis could not be performed because of inhomogeneity between the different trials. However, in the case of mortality rates we found it valuable to combine the available results but again without carrying out a proper meta-analysis (for the reasons mentioned). We agree with Professor Link that a few of the authors did not calculate mortality exactly on day 30, but we tried to extrapolate the data as closely as possible to this criterion. We disagree that one of the studies was not randomized[1]; a part of it was randomized, and only that part was included in the Review.

A recent proper meta-analysis of the available data on mortality rates after hip surgery in patients undergoing regional *versus* general anaesthesia[2] supports the conclusion in our paper. The debate continues on the potential advantages of regional *versus* general anaesthesia in surgical procedures. As emphasized by Professor Link, available studies are not directly comparable and therefore hinder exact interpretation. We still find it valuable to draw potential clinical conclusions despite these flaws. We maintain our conclusion that regional anaesthesia should be used whenever possible in patients undergoing hip surgery, based on the morbidity data so far published[3].

Statistical comment

Sir

I tend to agree with the criticisms in Professor Link's letter. The original Review omits a number of crucial details, which makes it very difficult to be confident that the 'meta-analysis' is sound. In particular there is no description of the methods used to identify relevant studies to be included, there is no description of the statistical methods used to combine the studies, and the conventional plot showing the confidence intervals for the relative risk from each study is omitted.

However, it is relevant to point out that the paper was published in 1988, when the art of meta-analysis was less well developed than it is today. Is a debate on this paper relevant, or has it been overtaken by other trials published in the area since 1988?

Pneumothorax during laparoscopic dissection of the diaphragmatic hiatus

Sir

The letter by Mr Reid and colleagues (*Br J Surg* 1993; **80**: 670) highlights the risk of pneumothorax during laparoscopic dissection of the oesophagus. Certainly the proximity of the left pleura mandates careful dissection to avoid puncture with resultant pneumothorax. We agree that conversion to an open procedure is not always required if pneumothorax results.

However, pneumothorax does not always produce hypotension and hypoxia during laparoscopic dissection. A chest drain is not always required, and the operation does not always need to be halted if pneumothorax is suspected so as to confirm the diagnosis by chest radiography and place a chest drain. Also, an insufflation pressure of 15 mmHg is probably excessive. We have found 10 mmHg to be sufficient for laparoscopic oesophageal dissection, reducing the risk of pneumothorax and pneumomediastinum.

During over 80 laparoscopic Nissen fundoplications, we have seen two cases of pneumothorax[1]. A 39-year-old man underwent laparoscopic fundoplication. During dissection of the oesophagus, the left pleura was visibly breached; the anaesthetist was informed of this. As there was no change in the patient's haemodynamic state or oxygen saturation as measured by pulse oximetry, the procedure was allowed to continue uneventfully. At the conclusion of the operation, a chest radiograph was obtained and confirmed a left pneumothorax. A chest drain was placed and removed on the first day after operation.

A 91-year-old man with a huge hiatal hernia and associated gastric volvulus underwent laparoscopic fundoplication with crural repair and anterior gastropexy. Insufflation with carbon dioxide distended a large hiatal hernia sac, enabling good vision of the hiatal structures. During dissection of the oesophagus, however, the left pleura was breached resulting in collapse of the hernial sac from gas entering the left pleural space, obliterating the view within the sac. Again, there was no associated hypoxia or haemodynamic compromise, enabling the procedure to progress uneventfully. Postoperative chest radiography showed pneumomediastinum but no pneumothorax. As carbon dioxide is highly water-soluble, small amounts of the gas in the pleural cavity will be rapidly resorbed.

While we agree with Reid *et al.* that pneumothorax associated with hypoxia and hypotension mandates stopping the operation to confirm the diagnosis, deflate the abdomen and place a chest drain, pneumothorax without associated problems does not require any of these manoeuvres. Postoperative chest radiography is probably sufficient. A small pneumothorax will resorb rapidly; a large pneumothorax is probably best managed by aspiration rather than chest drainage in the first instance.

Effect of suture material on tumour cell adherence at sites of colonic injury

Sir

We read with interest the article by Mr Reinbach and colleagues (*Br J Surg* 1993; **80**: 774–6) regarding the effect of suture materials on tumour cell adherence at sites of colonic injury and agree with the authors' recommendation that the anastomosis should be created using a suture with a low potential for tumour cell adherence. We feel, however, that previous studies have failed adequately to compare the influence of chemical and structural properties of sutures on tumour cell adherence.

We recently carried out an *in vitro* study on the adherence of malignant cells to suture materials, and compared chemically similar but topographically dissimilar materials and *vice versa*[1]. Significantly more cells adhered to both multifilament and protein-based sutures compared with monofilament and synthetic or metal sutures. Our results suggest that multifilament and protein-based sutures should be avoided to minimize the risk of malignant cell implantation.

Vibration white finger

Sir

I was disappointed to read the Review by Dr Palmer and Mr Collin (*Br J Surg* 1993; **80**: 705–9), which perpetuates the myth that the effects of chronic exposure to vibration are entirely vascular. The Stockholm Conference[1] in 1986 was called specifically to recognize the neurological effects. It was agreed that the condition should be renamed 'hand–arm vibration syndrome' to take account of these symptoms, and the Stockholm Workshop scale[2] was developed to define both vascular and neurological symptoms, and allow for each patient to be so graded. The Review quotes only the vascular part of the scale, so the sensorineural stages are given in *Table 1*.

Table 1 *Sensorineural stages of the hand–arm vibration syndrome*

Stage*	Symptoms
0SN	Exposed to vibration but no symptoms
1SN	Intermittent numbness with or without tingling
2SN	Intermittent or persistent numbness, reduced sensory perception
3SN	Intermittent or persistent numbness, reduced tactile discrimination and/or manipulative dexterity

*The sensorineural stage is established for each hand

I would not agree that common law damages or compensation for hand–arm vibration syndrome is a difficult matter and one that is rarely successful. A large number of cases have been successfully pursued through the courts, while others have been settled for appreciable sums.

The Royal College of Physicians report[3] can be commended for a full review of the condition.

Authors' reply

Sir

While it was not our intention to perpetuate any myths, our article concentrated on the vascular effects of chronic vibration exposure because these are the most important in terms of the suffering caused. This is illustrated by the fact that vibration white finger is the disease most commonly responsible for Disablement Benefit payments in the UK.

As regards common law damages for vibration white finger, the National Legal Officer of the General, Municipal and Boilermakers' Union, that perhaps most involved in this matter, agrees that it is an extremely difficult and unpredictable area of litigation and one that is rarely successful (J. O'Hara, personal communication). The principal difficulty is proving that the employer was negligent: this cannot be done in the great majority of cases.

Return to work after inguinal hernia repair

Sir

We were most interested in the Short Note by Dr Rider and colleagues (*Br J Surg* 1993; **80**: 745–6) on return to work after inguinal hernia repair. We recently carried out a postal questionnaire of 98 local general practitioners (GPs), asking how many days they advise a patient to stay off work after unilateral inguinal herniorrhaphy, using a similar

Table 1 *Times that practitioners advised patients to stay off work*

Type of work	Median (interquartile range) time (days)
Light	28 (21–35)
Moderate	42 (35–49)
Heavy	63 (49–84)

classification for type of occupation. We were surprised at the wide range of responses (*Table 1*).

It is clear that some GPs are considerably more enlightened than others in allowing earlier return to work. Interestingly, 20 per cent of them had some experience of patients who had undergone laparoscopic hernia repair, but only 56 per cent were sending these patients back to work sooner.

These findings reinforce the opinion that GPs are an important factor in delaying return to work after inguinal herniorrhaphy. We feel that it is the surgeon's responsibility to advise the GP and the patient regarding early return to work, and this may be especially important with regard to the laparoscopic technique, with which few GPs are yet familiar.

Announcement

The British Journal of Surgery Society SRS Prize

The British Journal of Surgery Society is to make a generous annual donation of £500 to the Surgical Research Society to be used as a prize. The Committee of the SRS, on behalf of its membership, is pleased to acknowledge the gift with gratitude.

The SRS Committee has decided that the prize will be awarded for the best paper published in the *BJS* that originates from an SRS presentation in the preceding year. The Committee of the SRS will judge these papers at its January meeting and the prize will be announced and presented at the dinner of the SRS.

The SRS is pleased to maintain close ties with the Journal. Two months each year are special SRS issues and contain most of the papers from presentations made to the SRS. It is hoped that this prize will encourage more presenters of SRS papers to prepare manuscripts without detracting from the principle of the SRS to enjoy receiving reports of work in progress. Papers not making publication in the SRS issues *will not be ineligible* and the winner of the Patey Prize *may* submit a paper and be equally eligible. It should be noted that any paper submitted as a result of presentation to the SRS passes through the same rigorous process of referee analysis and editorial criticism by the Journal; publication is not guaranteed.

SRS authors should identify the January or July meeting of the presentation on the submitted manuscript. Papers will automatically be collected and reviewed for the prize. Those already published in 1993 issues will automatically be included for consideration of the prize to be awarded for the first time in January 1994.

'Thank you' to The British Journal of Surgery Society for fostering and encouraging surgical research.

Book reviews

Current Surgical Practice

M. Hobsley, A. Johnson and T. Treasure (eds). 232 × 155 mm. Pp. 203. Illustrated. 1993. Sevenoaks, Kent: Edward Arnold. £32·50.

The sixth edition of this popular series maintains the traditions of its predecessors, highlighting the areas of growth and change in surgical practice. The present volume is arranged in two parts, the first a report of a symposium on decision making in surgery, the second invited contributions from experts.

The symposium encompasses articles on rational decision making in surgical practice, and the timing and rationale for the withholding or withdrawal of medical treatent. Audit, a most topical issue, is dealt with by a broad-ranging article that presents not only the methodology of audit but the rationale for it and the likely patient benefits to be achieved by it. The benefits and resource implications of day surgery, presently being encouraged by the Royal Colleges and Health Authorities, are presented in a balanced fashion, stressing the necessity of adequate patient selection and resourcing of the venture.

The invited contributions include a review of the management of gallstone disease, including an appraisal of the latest technological advances. The palliative approach to the treatment of oesophageal cancer, presenting largely the South African experience, favours either surgery or radiotherapy and somewhat dismisses the value of intubation, laser treatment or chemotherapy, conclusions that are unlikely to be universally accepted. Infective and non-infective complications in the immunosuppressed surgical patient are reviewed, as are current advances in the flap technology of plastic and reconstructive surgery. The management of hand injuries is clearly and concisely presented, and a further article ably overviews the pathological and clinical features of spinal cord compression.

The difficulties of keeping up to date with advances in specialties outwith one's own are made less onerous by a volume such as this. The popularity of this series testifies to its value to the generalist and to those approaching examinations in a variety of disciplines.

Modern Concepts in Surgery

S. K. Srivastava (ed.). 280 × 216 mm. Pp. 494. Illustrated. 1992. New Delhi: McGraw-Hill. US$24·95.

This is a surprising book. The first surprise is that it runs to 494 pages yet costs only US$24·95. The second surprise is that it originates from India and is intended as a practical guide 'to assist surgeons working under varying degrees of limitations and sophistication'. Given the state of the world, producing such a practical guide at modest cost seems highly commendable. So, does it achieve the stated aims?

The first chapter on modern imaging techniques gets the book off to an unfortunate start given the disparaging remarks that are made about reliance on high-tech non-invasive diagnosis in the preface. Sadly, this inconsistency is present throughout. Expensive modern techniques, such as imaging and parenteral nutrition, are described in some detail without trying to assess their strengths and weaknesses in the context of healthcare in the developing world. The chapter on endoscopy devotes a surprising amount of space to descriptions of proctoscopy and rigid sigmoidoscopy. By contrast there is only a rather superficial account of diagnostic laparoscopy, which can be performed with simple equipment and which has considerable application when resources are limited.

Even if the book does not achieve its aim it is still a reasonable surgical text and a bargain at the price. I would not recommend it for trainees in the UK, but it will probably sell well in many other countries.

Pancreatic Fistulas

P. Pederzoli, C. Bassi and S. Vesentini (eds). 235 × 154 mm. Pp. 212. Illustrated. 1992. Heidelberg: Springer. DM 168.

My attitude to conference proceedings is usually less than enthusiastic, but this volume does constitute an exception. The authors have selected a topic that, although narrow and specialized, nevertheless constitutes a difficult problem that is often poorly treated.

This volume covers the anatomy, physiology, pathogenesis, diagnosis, and medical and surgical treatment of pancreatic fistula in great detail. The authorship is truly international and very authoritative. The book is well printed and well illustrated. While most of the contributions review specific aspects of pancreatic fistula, such as 'Pancreatic fistulas in chronic pancreatitis', 'Pancreatic fistulas in pancreatic transplantation' and so on, there are sufficient original data and anecdotal material to make this a useful volume for the practising surgeon or gastroenterologist. It certainly deserves a place in the library of most large hospitals and constitutes a valuable asset to the surgeon or gastroenterologist with an interest in pancreatic disease.

Imaging for Surgeons

D. Lisle. 251 × 189 mm. Pp. 296. Illustrated. 1993. Sevenoaks, Kent: Edward Arnold. £65.

This is an excellent hardback reference book that should appeal to both surgeons in training and established consultants. The text is clearly laid out, succinct, yet reasonably comprehensive. The bulk of the book is full of radiographs and images from computed tomography (CT) and magnetic resonance imaging (MRI); some are excellent but unfortunately the quality of reproduction is somewhat variable. The book covers a wide range of surgically related topics, including abdominal trauma, postoperative complications and investigations of the skull and face, and these should be valuable to the surgeon in training. The information provided on the interpretation and relative merits of ultrasonography, CT and MRI will appeal to all. Particularly valuable are the recommendations for a particular investigation in specific circumstances (e.g. MRI rather than CT or *vice versa*). This book fulfils a useful function, bridging radiology and surgery, and would be a valuable asset to a surgical library.

International Surgical Practice

D. J. Leaper and F. J. Branicki (eds). 240 × 160 mm. Pp. 415. Illustrated. 1992. Oxford: Oxford University Press. £27·50.

As international travel becomes ever more commonplace and migration of people from one part of the world to another increases, it behoves the surgeon to become familiar with conditions not normally seen in everyday practice. This book provides a series of 21 articles that update the reader on topics as diverse as head injury, hepatocellular carcinoma and the surgical management of tropical disease in Asia. The editors have chosen an impressive and international list of contributors who generally write with authority from large personal experience. Some contributions particularly stimulated my interest. Professor Huang from Beijing gives a very succinct account of 1874 patients with squamous carcinoma of the oesophagus treated at his institute. A method of treating gastric cancer using 'immunochemosurgery' is described by Professor Jin-Pok Kim from Seoul showing good 5-year survival figures. The very large experience of managing patients infected with human immunodeficiency virus at Lusaka, Zambia, makes the article written by Professor Bayley and colleagues essential reading.

Although I thoroughly enjoyed reading this book, some of the illustrative material was disappointing. The quality of the operative photographs in the first chapter on 'Tropical diseases in Asia' is poor, as is some of the ultrasonographic hard copy in the same article. I enjoyed reading the account of 'Surgery of the parotid: how I do it', but would question the wisdom of including 16 black and white operative and clinical photographs when line diagrams would have served the purpose much better. Despite these caveats the book is well worth purchasing whether you are a trainee or an established surgeon. My copy is already well used.

Tutorials in Clinical Surgery in General. Vol. 2

F. G. Smiddy. 215 × 137 mm. Pp. 403. Illustrated. 1993. Edinburgh: Churchill Livingstone. £22·50.

Tutorials in Clinical Surgery in General is the second unreferenced and unindexed text targeted at pre-Fellowship trainee surgeons. It aims to provide tutorials in 32 topics and very largely succeeds. The book is succinct, authoritative yet hugely readable, which must be a godsend for the tired registrar preparing for examinations late into the night. The amount of detail is somewhat variable, doubtless reflecting the author's personal interest. At the risk of nit-picking I thought the paragraph describing the medical treatment of bladder outflow tract obstruction merited expansion and I would expect the Fellowship candidate to have a more detailed understanding of ductal carcinoma *in situ* of the breast and the management of benign breast disease than can be found in these pages.

In summary, this book provides a superb range of surgical topic tutorials written by an experienced examiner and justifies its publisher's claim to be essential reading for the Fellowship candidate. At a cost of £22·50 it is also excellent value.

P. A. Jones

Maidstone Hospital
Kent ME16 9QQ
UK

Updates in Colo-Proctology

J.-C. Givel, G. D. Oates and J. P. S. Thomson (eds). 234 × 154 mm. Pp. 251. Illustrated. 1992. Heidelberg: Springer. DM 138.

Papers on a wide variety of topics are summarized and grouped into sections covering surgical technique, cancer, inflammatory bowel disease and the complications of surgery. These papers vary greatly in their scientific content. Some are anecdotal reports of a few interesting cases, while others are substantial scientific works – such as 'Endoscopic diagnosis of anal intra-epithelial neoplasia', which suggests important parallels in the pathogenesis of anal neoplasia with that of neoplasia of the cervix. The morbidity associated with restorative proctocolectomy is reported in several papers but appears not to have dimmed the enthusiasm of its protagonists. Excellent round-table discussions of management of rectal cancer and complex fistula *in ano* make interesting reading.

This small publication of proceedings of a meeting held in 1990 is of variable quality and difficult to recommend unreservedly to either the Fellowship candidate or the established coloproctologist. It would be interesting to pick up in the library to browse through.

Instructions to authors

The British Journal of Surgery publishes original articles, reviews and leading articles. Short notes, case reports and surgical workshops are also accepted. All manuscripts are submitted to editorial review.

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another journal, has not been accepted for publication elsewhere and has not already been published. **Any detected attempt at dual publication will lead to automatic rejection and may prejudice acceptance of future submissions.** Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title page should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies of original articles and other editorial matter to: The Senior Editor, *The British Journal of Surgery*, Blackwell Scientific Publications Ltd, 25 John Street, London WC1N 2BL, UK. Telephone: 071-404 1831. Facsimile: 071-404 1927.
Books for review should be sent to the same address.

A covering letter must accompany all submissions and must be signed by all authors. The covering letter should state if an abstract of the work has been published and whether the authors wish the manuscript and/or illustrations to be returned if the work is not accepted. The first named author is responsible for ensuring that all authors have seen and approved the manuscript and are fully conversant with its contents.

Rejected manuscripts will not be returned to the authors, unless this is specifically requested.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached. Written consent must be obtained from the patient, legal guardian or executor for publication in *The British Journal of Surgery* of any details or photographs which might identify an individual. Evidence of such consent should be submitted with the manuscript.

Preparation of manuscripts

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65, or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from The Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR, UK (cost £1·00 per copy).

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. **When quoting specific materials, equipment and proprietary drugs, authors must state in parentheses the name and address of the manufacturer.** Failure to do so will result in delay in publication as the Journal considers that this information is essential for any reader who wishes to obtain similar material. Generic names should normally be used.

Original articles

Original articles should normally be in the format of introduction, methods, results, discussion. Each manuscript should contain a summary on a separate page. Authors are reminded that there is considerable pressure on editorial space in the Journal. Lengthy manuscripts are likely to be returned to authors for shortening. The discussion in particular should be clear and concise, and should be limited to matters arising directly from the results. Authors should avoid discursive speculation.

Reviews

The Editorial Board of *The British Journal of Surgery* encourages submission of review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium. Potential authors seeking advice on the suitability of review topics are advised to contact: Mr J. A. Murie, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Leading articles

The Editors commission signed leading articles to *The British Journal of Surgery*. These articles are 600–1000 words in length, address controversial topics of current interest and are supported by key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium is payable on publication.

Short notes

These are original observations presented in brief form. They should follow the standard format of introduction, methods, results and discussion, but no summary is required. Short notes should not exceed 500 words with a maximum of five references and one table or one figure.

Case reports

The British Journal of Surgery receives an increasing number of case reports each year. Space within the Journal remains at a premium and the rejection rate is high. Case reports should be no more than 400 words (300 if accompanied by a figure), with no more than five references and one illustration.

Surgical workshops

These describe technical innovations or modifications which may be useful in surgical practice. These articles should be less than 500 words long; they may be accompanied by no more than two figures and up to five references.

Typescripts

It is *essential* that manuscripts be clearly reproduced with adequate space for editorial notes. **Papers must be typewritten or printed on A4 paper (210 × 297 mm) on one side of the paper only with double spacing and 4 cm margins. Manuscripts which do not conform to these requirements will be returned to the authors for recasting.** Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations. The text should usually follow the standard sequence of introduction,

methods, results and discussion. These sections should run sequentially through the text, avoiding blank space between them.

Title page

The title page should give: (1) the title of the article; (2) the name and initials of each author; (3) the department and institution to which the work should be attributed; (4) the name, address, and telephone and facsimile numbers of the author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; and (6) the category in which the manuscript is being submitted (original article, case report etc.).

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytical methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Three copies of all illustrations and tables should be submitted. Each table with an appropriate brief title should be typed on a separate page. At least one set of illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Photocopies should be of sufficient quality to enable the Journal's referees to judge their content and value. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers of patients involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full. Permission to use published work must be obtained from the original author and the publisher before submission.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text and must be clearly defined on first use.

Numbers and units

The decimal point, not a comma, is used, e.g. 5·7. A space and not a comma follows thousands and multiples thereof, e.g. 10 000. SI units (International System of Units) should be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

References

References should be typed with double spacing and cited in the Vancouver style (see above: Uniform Requirements for Manuscripts Submitted to Biomedical Journals). Reference to abstracts from meetings is discouraged; reference to unpublished communications is not acceptable. Personal communications should be cited in the text, in parentheses. The first author is responsible for confirming the acceptability of the material quoted with the originator.

In the text, references should be numbered consecutively by superscript: ^{1,2} or $^{1-3}$. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication; volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; **66**: 184–6. The sequence for the chapters of a book should be: author(s); chapter title; editors; book title; place of publication; publisher; year of publication; page numbers. For example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In: Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications.* New York: Springer-Verlag, 1981: 123–63.

Statistics

For detailed guidance on the handling of statistical material, authors should consult *The British Journal of Surgery* 1991; **78**: 782–4. The Editors and statistical referees in evaluating a manuscript will consider the *design* of the study, the *presentation* of the data, the *analysis* of the data, and the *interpretation* of the results.

Design

Authors should set out clearly the objectives of the study, should identify the primary and secondary hypotheses, and should explain the rationale for the choice of sample size.

Presentation

Whenever possible a graphical presentation should be used to illustrate the main findings of a study. The use of standard deviation and standard error should be clearly distinguished. The use of the '±' symbol should be avoided; these statistics should be presented in parentheses after the mean value.

Analysis

There should be a clear description of which methods were used for which analyses, and any methods not in common usage should be supported by references. Results of statistical tests should be reported by stating the value of the test statistic, the number of degrees of freedom and the P value. For example, '$t = 1{\cdot}34$, 16 d.f., $P = 0{\cdot}20$' might be reported. Actual P values should be reported, to two decimal places, especially when the result is not significant, rather than stating 'not significant'.

Whenever possible, the results of the primary analyses should be reported using confidence intervals instead of, or in addition to, P values.

Interpretation

Statistical significance should not be confused with clinical significance. In particular, 'negative' findings should be interpreted through the use of confidence intervals.

Authors should beware of placing undue emphasis on secondary analyses, especially when they were suggested by an inspection of the data.

RECONSTRUCTIVE UROLOGY

Edited by G Webster, R Kirby, L King and B Goldwasser

The minimally invasive techniques of lithotripsy and laparoscopy have eliminated many of the previously traumatic procedures in urology. However, reconstructive urology continues to involve major surgical procedures and remains the largest component of the discipline. Reconstructive urology is concerned with the correction of congenital defects and those caused by malignancy and trauma, as well as incontinence; conditions which often require a considerable amount of surgery and a wide view of the genitourinary system which is only available through traditional surgery. This book is the most exhaustive reference work to date on reconstructive urology.

- written by a distinguished international team;
- despite the dominance of minimally invasive techniques in other branches of urology, reconstructive urology remains a major and growing field;
- provides detailed coverage of every aspect of the field, from functional anatomy to surgical technique.

Contents:

Sectional Contents: Part 1 - Basic Science; Part 2 - Evaluation; Part 3 - Principles of Reconstruction; Part 4 - Renal Reconstruction; Part 5 - Ureteral Reconstruction; Part 6 - Reconstruction of the Bladder; Part 7 - Reconstruction of the Urethra; Part 8 - Urogynecologic Reconstruction; Part 9 Reconstruction of the Penis; Part 10 - Reconstruction of the Testis and Scrotum.

Hardback, £175.00, Jan-93, 1200 pages, 826 illustrations, 086542229X

ABRIDGED PRESCRIBING INFORMATION
CIPROXIN® TABLETS
(Refer to data sheet before prescribing)

Presentation White tablets containing the quivalent of either 250mg, 500mg or 750mg ciprofloxacin. **Uses** Ciprofloxacin is ndicated for the treatment of single or mixed nfections caused by susceptible organisms. Also indicated for prophylaxis against nfection in elective upper gastro-intestinal urgery and endoscopy where there is an ncreased risk of infection. **Dosage and administration** The tablets should be swallowed whole with liquid. ***Adults:*** 250–750mg twice daily. In surgical prophylaxis a single 750mg tablet administered 60–90 minutes before the procedure (but see interactions with oral premedicants). ***Duration of treatment*** For acute infections the usual treatment period is 5 to 10 days, except in cases of acute uncomplicated cystitis where treatment is 250mg twice daily for 3 days. Generally, in acute and chronic infections where sensitivity is proven, treatment should be continued for at least 3 days after the signs and symptoms of infection have disappeared. ***Elderly*** No dose adjustment. **Contra-indications** Hypersensitivity to ciprofloxacin or other quinolones; also in children and growing adolescents except where the benefits of treatment outweigh the risks. **Warnings and precautions** Use with caution in epileptics and patients with a history of CNS disorders. Treatment could result in impairment of ability to drive or operate machinery. Crystalluria has been reported so patients should be well hydrated and excessive urine alkalinity avoided. As haemolytic reactions with ciprofloxacin are possible in patients with latent and actual defects in glucose-6-phosphate dehydrogenase activity, use with caution. **Drug interactions** Increased plasma levels of theophylline have been observed following concurrent administration with ciprofloxacin. The dose of theophylline should be reduced and plasma levels of theophylline monitored. Where monitoring of plasma levels is not possible, avoid the use of ciprofloxacin in patients receiving theophylline. Particular caution is advised in those patients with convulsive disorders. Interactions have also been noted with anticoagulants and cyclosporin. The tablets should not be administered within 4 hours of medications containing magnesium, aluminium or iron salts. High doses of quinolones have shown an interaction with NSAIDs in animals leading to convulsions. Administration of quinolones and glibenclamide simultaneously can potentiate the effect of glibenclamide, resulting in hypoglycaemia. Opiate premedicants or regional anaesthetic agents must not be administered concomitantly with ciprofloxacin when used for surgical prophylaxis. **Use in pregnancy and lactation** Not recommended. **Side-effects** Gastro-intestinal, CNS, hypersensitivity/skin reactions, musculoskeletal and special sense disturbances. Renal and hepatic disturbances. Effects on haematological parameters. Also reported: vasculitis, pseudomembranous colitis, Stevens-Johnson Syndrome, Lyell Syndrome, haemolytic anaemia, granulocytopenia, intracranial hypertension, petechiae, haemorrhagic bullae, tenosynovitis and tachycardia. **Overdosage** Serum levels of ciprofloxacin are reduced by dialysis. **Legal category** POM. **Package quantities** Blister strips of 10 in packs of 10, 20, and 100 tablets. **Product licence numbers** PL0010/0146–0148. **Basic NHS cost** 250mg x 10 tablets £7.50, 500mg x 10 tablets £13.75, 750mg x 10 tablets £20.00. **Date of preparation** July 1993

750mg Ciproxin® tablet

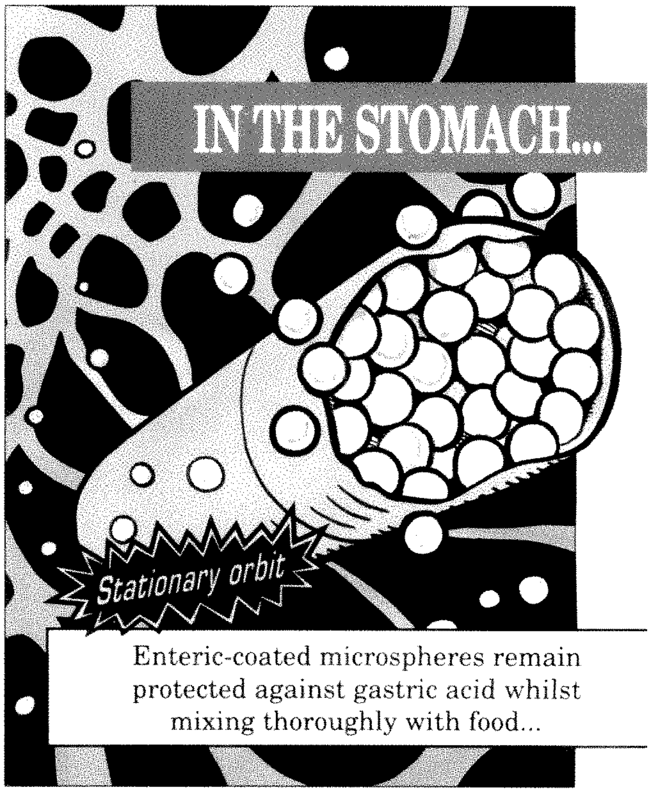
ciprofloxacin

Ciproxin® 750mg

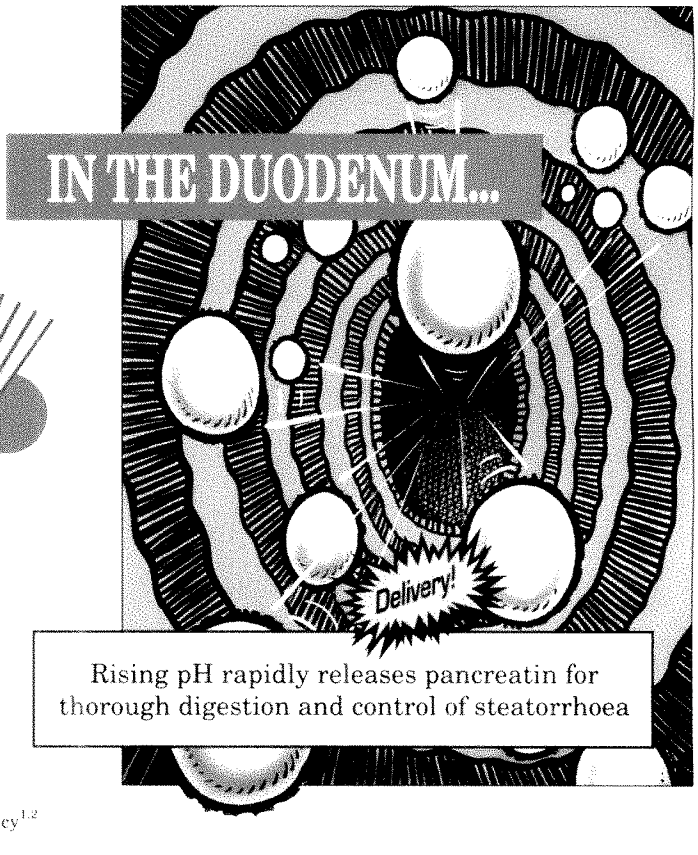
ciprofloxacin

Now indicated for upper GI Surgical Prophylaxis

A REAL FORCE IN PANCREATIC EXOCRINE INSUFFICIENCY



Enteric-coated microspheres remain protected against gastric acid whilst mixing thoroughly with food...



IN THE DUODENUM...
Delivery!

Rising pH rapidly releases pancreatin for thorough digestion and control of steatorrhoea

creon®
pancreatin 25000

Superior control of steatorrhoea†

† Compared with standard enteric-coated tablets in pancreatic insufficiency[1,2]

Prescribing Information

Presentation: Opaque orange yellow, hard gelatin capsules containing brownish coloured enteric coated pellets of pancreatin, equivalent to

25,000 PhEur units of lipase
18,000 PhEur units of amylase
1,000 PhEur units of protease (total)

Available in packs of 50. Basic NHS price £19.50

Indication: Pancreatic exocrine insufficiency

Dosage and Administration: Adults (including elderly) and children: Initially one capsule with meals, then adjust according to response. The capsules can be swallowed whole, or for ease of administration they may be opened and the granules taken with fluid or soft food, but without chewing. If the granules are mixed with food it is important that they are taken immediately, otherwise dissolution of the enteric coating may result.

Contra-indications, Warnings, etc. Contra-indications: Substitution with pancreatic enzymes is contra-indicated in the early stages of acute pancreatitis. Warnings: Use in pregnancy: There is inadequate evidence of safety in use during pregnancy. The product is of porcine origin. Rarely cases of hyper-uricosuria and hyper-uricaemia have been reported with very high doses of pancreatin. Overdosage although not experienced until now, could precipitate meconium ileus equivalent. Perianal irritation, and rarely, inflammation, could occur when large doses are used.

By launching the finest needle ever fixed on a prefilled syringe, the necessary penetration force has been reduced by 23%. This has been achieved due to:

- extremely low external diameter of the needle
- improved quality of the needle surface
- low angle of the needle point

*Data on file, Kabi Pharmacia

FRAGMIN®
Abbreviated Prescribing Information

Presentation: Single dose disposable syringes containing dalteparin sodium 2,500 I.U. (anti-Factor Xa)/0.2ml or 5,000 I.U. (anti-Factor Xa)/0.2 ml. No preservative present. **Indication:** Peri- and post-operative surgical thromboprophylaxis. **Dosage:** Adults only. *Moderate risk of thrombosis.* Fragmin 2,500 I.U. administered subcutaneously (s.c.) 1-2 hours prior to surgery and thereafter 2,500 I.U. s.c. once-daily for five days or until the patient is fully ambulant. *High risk of thrombosis* eg. elective hip replacement, extensive operations, patients with malignant disease. Fragmin 2,500 I.U. administered s.c. 1-2 hours prior to surgery, and the same dose is administered 12 hours later. Thereafter 5,000 I.U. s.c. once-daily for five days or until the patient is fully ambulant. **Contraindications:** There are no known absolute contraindications to Fragmin. However, caution should be exercised in patients with an increased risk of bleeding complications. **Precautions:** Caution in patients with severely disturbed hepatic or renal function, thrombocytopenia, or defective platelet function and in patients receiving drugs affecting coagulation/platelet function; patients with known heparin hypersensitivity. Fragmin, when administered in doses of 2,500-5,000 I.U./day, does not generally accumulate and, therefore, monitoring of anti-Factor Xa levels is not usually necessary. **Side effects:** High doses of Fragmin with serum anti-Factor Xa levels greater than 1.5 I.U./ml may cause bleeding. Slight to moderate increase in liver enzymes. The following heparin side effects cannot be excluded as Fragmin is a derivative of heparin; thrombocytopenia, allergic reactions, osteoporosis. **Overdose:** 100 I.U. Fragmin is inhibited by 1mg protamine: see data sheet for full prescribing information. **Legal Category:** POM. **Packs:** Fragmin 2,500 I.U./0.2ml: basic NHS price of £ 25.95, pack of 10 single dose syringes. 5,000 I.U./0.2ml: basic NHS price of £ 36.95 pack of 10 single dose syringes. **P. L. Numbers:** 2,500 I.U./0.2ml 0022/0076. 5,000 I.U./0.2ml 0022/0077. **Further information is available from: Kabi Pharmacia Ltd, Davy Avenue, Knowlhill, Milton Keynes, Bucks MK5 8PH.** ® DENOTES REGISTERED TRADEMARK OF KABI PHARMACIA

Restorative Proctocolectomy

Edited by R J Nicholls, D C C Bartolo and N J Mortensen

Proctocolectomy, the removal of the colon and rectum, is necessary in serious cases of diseases which affect the whole large intestine (such as ulcerative colitis or polyposis) or in functional bowel disease. In the past this has necessitated leaving the small intestine open to the exterior, involving the use of a colostomy bag.

Restorative proctocolectomy is a relatively new treatment whereby the surgeon removes the large intestine, then joins the small intestine to the anus, which is left in place. The advantage of this technique is that it allows the patient to maintain a fair degree of normal function.

Written by leading experts from the USA, Europe, South Africa and the UK, with extensive references and numerous illustrations, this will be the definitive book on this new technique.

- covers the basic science, pathology, operative technique, results, and history and background of a new and innovative technique;
- the definitive book on the subject, written by leading experts who have helped to establish the procedure;
- includes chapters on controversies and complications;
- contains exhaustive and up to date references.

Contents:

Introduction; History; Background; Case selection/counselling polyposes?; Constipation; Techniques; Controversies in pouch construction; Complications, management, failure, revisions; Physiology studies/functions - early - late; Physiology studies/pouch function; Pouchitis/microbiology/dysplasia, new colitis in pouch; Pouch ecology; Pouch pathology.

Certificate Number: FM 14713

Relied upon by leading surgeons, Swann-Morton blades are as worldwide as their reputation for quality.

Alongside their classic surgical range, there are the "Major" orthopaedic blades, "Minor" disposables, and special blades for cervical biopsy and myringotomy. Most recent is the completely new "Fine" range.

Extensively researched, all blades are produced under strict quality control by precise automation, and inspected at every stage.

Swann-Morton always have the blade for the task, uniformly correct in shape, size and weight, and durably sharp – that's why they are famous worldwide!

Peritonitis

Edited by D Fry

There have been considerable advances in the care of patients with peritonitis, including major strides in diagnosis, specific surgical care, anaesthetic techniques and supportive measures, including the use of antibiotics.

However, there are still patients who remain unresponsive, typically those with other serious illnesses. The treatment of such challenging cases requires a reexamination of the entire theory and process of treatment of peritonitis. This book furthers such a reassessment and will be of particular benefit to those involved in the front-line care of peritonitis sufferers.

- comprehensive coverage from pathophysiology to methods of treatment;
- a timely review of peritonitis and its management;
- both scientific and practical questions are covered.

Contents:

Pathophysiology of peritonitis; Hemodynamic and metabolic aspects of peritonitis; Diagnosis of peritonitis; Supportive care of the peritonitis patient; Mechanical therapy in peritonitis; Radiologic strategy in the management of intra-abdominal abscess; Antimicrobial chemotherapy in peritonitis; Antibiotic pharmacology in peritonitis; Special problems in peritonitis - primary peritonitis; Special problems in peritonitis - pediatric peritonitis; Special problems in peritonitis - peritonitis from the biliary tract and pancreas; Special problems in peritonitis - endometritis, salpingitis, pelvic peritonitis; Special problems in peritonitis - intercurrent nosocomial infection; Multiple system organ failure and peritonitis; Future considerations in the management of peritonitis

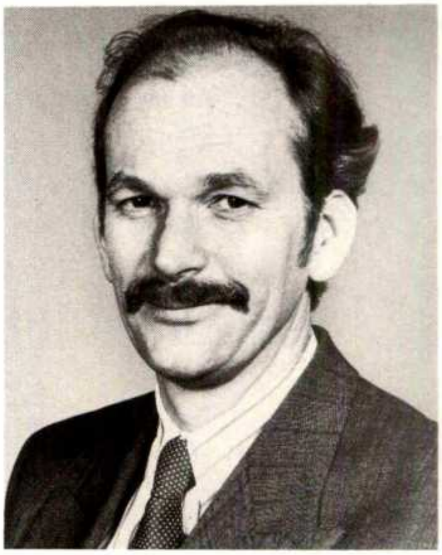
Overseas Members of the Editorial Board

Br. J. Surg. 1993, Vol. 80,
November, 1361–1362

Further Board Members from around the world.

PROFESSOR FLEMMING STADIL
(Denmark)

Flemming Stadil (born 1938) has been Professor and Chairman of Surgical Department C at the National University Hospital in Copenhagen for the past 10 years. He graduated from Aarhus in 1964 and trained at various hospitals in Copenhagen. In 1978 he was appointed Chief Surgeon at Herlev University Hospital and in 1983 Professor of Surgery at Rigshospitalet. He has been General Secretary of the Danish Surgical Society, President of the Danish Society of Gastroenterology and President of the Scandinavian Surgical Society (1991–1993). His main interest is in gastrointestinal surgery including the physiology and endocrinology of the intestinal tract.



MR MARTIN COOPER
(Exeter)

Martin John Cooper (born 1947) is a consultant surgeon at the Royal Devon and Exeter Hospital. He qualified from the Royal Free Hospital, London, where he undertook house officer posts before moving to the South-west of England. Surgical training in Bristol and Plymouth was complemented by a research fellowship in Chicago. He became successively Lecturer and Consultant Senior Lecturer at Bristol before moving to his present post in 1988. He is Secretary of the Pancreatic Society of Great Britain and Ireland and has wide interests in upper gastrointestinal and HPB surgery.

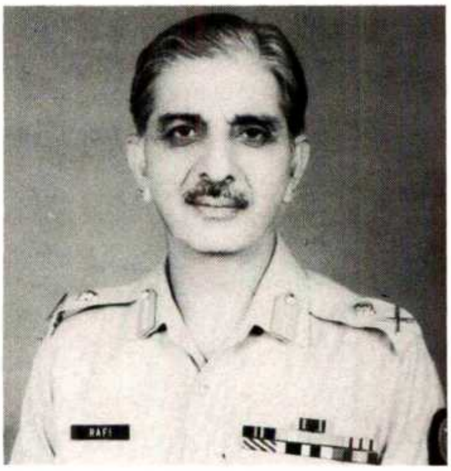
DR JAMES YAO
(USA)

James S. T. Yao is Magerstadt Professor and Chief of Vascular Surgery at Northwestern University Medical School, Chicago, Illinois. He graduated in Taiwan and trained in Chicago (Cook County Hospital) and London (St Mary's Hospital), where he obtained a PhD in vascular physiology. Within vascular surgery his particular interests have included arterial and venous thrombosis, and non-invasive diagnostic techniques. He has co-edited the *Year Book of Vascular Surgery* and is a past president of the Society for Vascular Surgery.

0007-1323/93/111361–02 © 1993 Butterworth–Heinemann Ltd

PROFESSOR KRZYSZTOF BIELECKI
(Poland)

Krzysztof Bielecki was born in 1938 and graduated from the School of Medicine in Warsaw in 1960. His surgical training was cosmopolitan, involving spells in the then Czechoslovakia, Hungary, Sweden, Britain and the USA, as well as Poland. Since 1988 he has been Professor and Chairman of the Department of Surgery at the Medical Centre for Postgraduate Education in Warsaw. His particular interests are in gastric, pancreatic and colorectal surgery.



MAJOR-GENERAL C. M. RAFI
(Pakistan)

Chaudhary Muhammad Rafi (born 1937) is Professor and Head of the Surgical Department at the Army Medical College in Rawalpindi. He graduated from King Edward Medical College, Punjab University, Lahore before joining the Armed Forces Medical Services of Pakistan. His training included 2 years in the UK. He has risen through the ranks, both military and academic, becoming a professor in 1985 and a general officer in 1993.

DR MOSHE SCHEIN
(Israel)

Moshe Schein was born in 1950 and graduated from the Hebrew University and Hadassa Medical School in Jerusalem. He spent 5 years training in surgery in Johannesburg, South Africa, where he was appointed a consultant senior lecturer in the University of Witwatersrand in 1986. He returned to Israel to take up his present post as Deputy Head of Surgery at Rambam Medical Centre, Haifa in 1991. Within general surgery he has interests in vascular surgery, infection and trauma.

PROFESSOR EERO KIVILAAKSO
(Finland)

Eero Kivilaakso (born 1942) is Professor of Surgery at the University of Helsinki, where he graduated in 1968, and Chief of the Second Department of Surgery at Helsinki University Central Hospital. His training was in Helsinki and Boston, USA, where he spent 2 years at Beth Israel Hospital. He is a former president of the Finnish Gastroenterological Society. A surgical gastroenterologist, his main interests lie in oesophago-gastric and pancreatic surgery.

Screening for abdominal aortic aneurysm

Ultrasonographic screening for abdominal aortic aneurysm (AAA) reveals a prevalence in men of 2·6 per cent in those aged 60–64 years (J. Hamer, personal communication), 6 per cent[1] at age 65–74 years and 9 per cent[2] in those over 75 years. In women the disease is less common and the age of onset 10–15 years later. The male:female risk ratio[3] of death from ruptured AAA is 11:1 at age 60–65 years, decreasing to 3:1 at 80–85 years. Three groups at increased risk of developing aortic aneurysm have been identified: patients with symptomatic occlusive arterial disease, cigarette smokers, and first-degree relatives of patients with AAA. For men with intermittent claudication or coronary artery disease the relative risk is two to three times that of the general population, while for first-degree male relatives of patients with aneurysm the risk is increased fivefold[4].

The ideal screening programme for AAA would focus resources on an easily identifiable population old enough to have developed the disease but young enough to benefit from prophylactic surgery. The Gloucestershire community screening programme[5] for AAA is now screening men in their 65th year. At this age the prevalence of aneurysm 3·0 cm or more in diameter is 4·4 per cent and of those 4·0 cm and over 1·3 per cent. As all majestic oak trees from little acorns grow, so all clinically significant AAAs develop from small aneurysms detectable only by scanning. The growth rate of small aortic aneurysms is generally slow but accelerates as they increase in size. For those under 4·0 cm in diameter[6] the average growth rate is 0·2 cm per annum, while 6·0-cm aneurysms[7] grow at a mean of 0·5 cm per annum. Follow-up studies[6] on small AAAs have shown that 89 per cent grow less than 0·6 cm a year. Consequently, the smallest aneurysms detectable ultrasonographically are unlikely to reach a size at which most surgeons would recommend elective repair for at least 5 years. It follows that interval screening of men found not to have an aneurysm at 65 years is unlikely to be worth while until they have lived to three score years and ten. Large aneurysms grow quickly and rupture while small aneurysms grow slowly and usually do not, so inevitably most AAAs detected by screening are small. There is universal agreement that for an aneurysm of 5·5 cm or more in diameter elective surgical resection confers the best protection against premature death, even though the average operative mortality rate in the UK is likely to be nearer 8 per cent than the 4 per cent or less reported from some specialist units[8]. For patients with aneurysms of 4·5–5·4 cm there is general uncertainty whether survival beyond 12 months is more likely to be achieved by elective surgical correction or conservative management. Prospective randomized trials to resolve this doubt are currently in progress in Canada, the UK and the USA, with the latter two trials also including aneurysms of 4·0–4·4 cm diameter.

Fewer than 0·5 per cent of men aged 65 years will have an AAA 5·5 cm or more in diameter detected by prevalence screening, but a further 1–2 per cent will have smaller aneurysms that can be expected to grow to this size within 5 years. If one assumes that the annual incidence of aortic aneurysm 5·5 cm or more in diameter is 0·4 per cent in the 65–74 years age group, then screening men aged 65 years with interval ultrasonography at 70 years would render 40 patients aged 65–74 years per 10 000 per annum liable to elective aneurysm repair. Currently 13 men per 10 000 per annum in this age group in Oxford undergo elective and emergency surgery for AAA of at least 5·5 cm diameter. Even allowing for the 60 per cent of patients with aortic rupture who die at home or before surgery, there is still an annual discrepancy of 18 aneurysms per 10 000 at-risk population. What happens to almost half of all those with a large aortic aneurysm is unknown. Some will survive well into their eighth decade of life with a large intact aneurysm, others will die from unrelated natural causes. Some, no doubt, will die from unrecognized aneurysm rupture recorded for posterity as yet another death from myocardial infarction.

There is now no doubt that screening men at 65 years or more with abdominal ultrasonography will reveal many unsuspected AAAs; some will be clinically significant on detection and most will become so over the following decade. The fundamental question that remains unanswered is: Does it do any good? As with

0007-1323/93/111363-02 © 1993 Butterworth-Heinemann Ltd

screening for breast cancer this question can ultimately be answered only by a well organized randomized multicentre trial with follow-up to death. The weak link in any such study will be the unreliability of certified causes of death. In many cases unless autopsy is performed the recorded cause of death is little more than an inspired guess. It is likely that in screened patients known to have AAA the guess will include ruptured aneurysm, while in unscreened controls with an occult aneurysm it will not. Unless this problem can be satisfactorily resolved there is a danger that even a substantial benefit conferred by screening for aortic aneurysm will go unrecognized.

Without a screening programme there is still much that could be done to reduce the incidence of ruptured aortic aneurysm. Craig *et al.*[9] have shown that in the 2 years before aortic rupture one-quarter of patients with aneurysm had been diagnosed but most were not referred to a vascular surgeon. A further 38 per cent of patients had undergone medical examination without the aneurysm being noticed. Opportunistic screening of the aorta in elderly men presenting with other illness might achieve almost as much as a formal screening programme if the diagnosis of AAA always occasioned referral to a vascular surgeon.

Surgical options for primary hepatocellular carcinoma

Hepatocellular carcinoma (HCC) accounts for more than 1 million deaths each year worldwide and even quite small tumours, untreated, confer a poor prognosis – fewer than 13 per cent of patients are alive at 3 years[1]. Many patients with HCC will have chronic liver damage resulting from hepatitis B or C, and cirrhosis in more than three-quarters makes surgery hazardous. In advanced cases, only palliation with chemotherapy is possible. Tumour irradiation, alcohol injection and cryotherapy are current treatment options being explored. Transarterial catheter embolization has also been advocated and a 1-year survival rate of 50–78 per cent reported[2,3]. Nevertheless, complete tumour resection offers the only realistic prospect of cure. Should such liver resection be partial – or complete and followed by hepatic transplantation?

In the absence of cirrhosis, resection is the treatment of choice and can be undertaken with low morbidity and a hospital mortality rate of 3–15 per cent. The 5-year survival rate of patients with tumours less than 2 cm in size is high, although this decreases to between 20 and 37 per cent[4] when the tumour size exceeds 5 cm. Extended hepatic resection of tumours with major vascular invasion has been reported and results may be improved by preoperative chemotherapy. Complete hepatic excision followed by transplantation should be reserved for the relatively few non-cirrhotic patients who have cancer of all the major compartments of the liver but for whom staging indicates that malignancy is confined to this organ.

The surgical approach in patients with cirrhosis is less clearly defined. Resection rates are low with advancing or decompensating liver disease (Child's grade B or C) in which the risk of haemorrhage, infection and liver decompensation is significant. The degree of parenchymal hepatic reserve in patients with cirrhosis may be established by assessing synthetic function by measuring the serum albumin level and prothrombin time, as well as by standard liver function tests; bromsulphthalein or indocyanine green clearance may be included. Resection in patients with Child's grade B or C cirrhosis is usually confined to tumours less than 5 cm in size situated peripherally, which can be removed by non-anatomic or segmental excision, maximizing the residual liver mass. In such cases, mortality rates are below 10 per cent, but it is important that an adequate tumour clearance margin of at least 1 cm is achieved if local recurrence is to be avoided.

Patient survival frequently depends not only on the likelihood of tumour recurrence but also on the underlying stability of the cirrhosis. Progression of cirrhosis means that fewer than 30 per cent of patients with Child's grade B or C disease will avoid complications of variceal haemorrhage or hepatic decompensation. The 5-year survival rates are low (0–23 per cent)[5,6] because as many patients succumb to progression of cirrhosis as to recurrent tumour. Larger tumours or those situated more centrally may be irresectable because of inadequate hepatic reserve and even with modern surgical techniques mortality rates increase. Nagasue *et al.*[6] reported a 3-year survival rate of only 16 per cent in patients under 60 years of age with Child's B or C cirrhosis and tumours less than 5 cm in size or in those with multicentric HCC nodules. Such patients, they concluded, should be considered for transplantation.

The high rate of recurrence that marked the early disappointing results of transplantation was often the result of advanced tumour stage, with residual cancer in coeliac lymph nodes in a high proportion of patients; fewer than 20 per cent of such patients survived more than 2 years. However, Ringe *et al.*[7] showed that when coeliac nodes did not contain tumour approximately half of all patients survived for more than 3 years after transplantation.

In the European Liver Transplantation Registry[8], the 3-year survival rate of patients after transplantation for HCC is over 40 per cent, although this figure includes 'incidental' tumours. An attempt to address the issue of residual lymph node disease led previously to radical hepatic excision and *en bloc* clearance of the coeliac lymph nodes and adjacent tissue before transplantation – the so-called 'cluster' operation[9]. These complex procedures were largely abandoned when it became clear that the 2-year survival rate was less than 20 per cent in patients whose coeliac lymph nodes contained tumour[10]. In patients with negative lymph nodes (and so presumably not requiring such a wide radical foregut excision) the 2-year survival rate was more than 70 per cent, not significantly different from that of patients undergoing 'simpler'

0007-1323/93/111365–03 © 1993 Butterworth-Heinemann Ltd

hepatic transplantation[11]. In the light of this re-evaluation of the early experience of transplantation for HCC, meticulous cancer staging is now undertaken in patients with Child's grade B or C cirrhosis.

In south-east Asia small tumours less than 5 cm in size are routinely resected in compensated patients with Child's grade A cirrhosis and, provided that adequate tumour clearance is achieved, with good results. A 5-year survival rate of between 25 and 67 per cent has been reported[4], although tumour recurrence or the development of new multicentric HCC requires further treatment in some patients. Most Asian patients have non-alcoholic liver disease and some reports have included those with hepatitis who may not be cirrhotic. Indeed, Child's grades such as 'functional' A or B may be related to indocyanine green clearance and may be used in patients for whom histological analysis does not show cirrhosis. Parenchymal hepatic function in such patients may be good[4,6], with a normal coagulation profile and concentrations of bilirubin and albumin, and an indocyanine green clearance rate of over 85 per cent at 15 min. The results of HCC excision are good, with a low hospital mortality rate and 52·7 per cent of patients alive at 3 years. Even so, only 25 per cent of patients[6] survive to 8 years.

In many Western countries hepatitis B is less common and the Child classification is usually restricted to those with histologically confirmed cirrhosis, in whom outcome may be less certain. Among such patients a peripheral HCC less than 5 cm in diameter is rare and for centrally situated or large tumours the morbidity and mortality rates have been high when hemihepatectomy has been undertaken. The progression of cirrhosis in conditions such as haemochromatosis, chronic active hepatitis, primary biliary cirrhosis and alcoholic liver disease means that the risk of hepatic decompensation is significant. The uncertain prognosis of the underlying parenchymal liver disease combined with concern about recurrent or metachronous HCC, especially if inadequate tumour clearance occurs, has led to reappraisal of the benefits of complete hepatic resection and transplantation[12].

With improvements in immunosuppression and modification of the surgical techniques of hepatic transplantation, many elective patients can receive grafts safely with low morbidity, a mean hospital stay of less than 20 days and a hospital mortality rate under 8 per cent. Recent analysis of patients with cirrhosis and comparable tumour stage gave a 5-year survival rate of 35·6 per cent for those who underwent complete hepatic resection and transplantation, compared with no survivors among patients who had partial hepatectomy[11]. The use of neoadjuvant chemotherapy in patients receiving grafts for HCC may allow a wider selection of patients. One recent study[13] reported that 59 per cent of patients were alive at 3 years with 54 per cent disease-free when concomitant neoadjuvant chemotherapy was used. In over half of these patients the tumour size was greater than 5 cm.

Complete hepatic excision with liver transplantation is not appropriate for all patients with cirrhosis and careful assessment is needed, especially when alcoholic cirrhosis is the underlying disease. Against the benefits of transplantation must be balanced its significant cost, the need for life-long immunosuppression and the relative shortage of donor organs. Moreover, hepatitis B may recur in the grafted liver, in spite of hyperimmune globulin. While the option of transplantation is not appropriate for elderly patients with concomitant major disease, it should be considered for those of less than 60 years with underlying cirrhosis and a large central tumour or multifocal disease.

It is likely that in the immediate future the approach to the treatment of HCC in different countries will vary. In south-east Asia, where for cultural reasons cadaveric organ donation is not common and transplantation is rarely possible, skilled clinical teams will continue to achieve good short-term results using resection for small peripheral HCC in patients with mildly compromised hepatic function. Elsewhere, for patients with HCC and cirrhosis management protocols will increasingly include the complete range of options, both surgical and oncological, adding complete liver excision and transplantation to the standard technique of partial hepatectomy. Only by combining screening and earlier diagnosis of HCC with a wider range of complementary surgical options will the prognosis of this condition be improved.

Review

Br. J. Surg. 1993, Vol. 80, November, 1368–1373

Hepatocyte growth factor/scatter factor, liver regeneration and cancer metastasis

Hepatocyte growth factor (HGF) is the most potent stimulator of hepatocyte growth and DNA synthesis identified; it is now known to be the same molecule as scatter factor, which increases the motility of a variety of cell types. HGF is becoming recognized as one of the most important factors in the regulation of liver regeneration after surgical resection or chemical damage. HGF is produced by several tissues, including neoplasms; it can therefore provide a stimulus for increased motility of malignant cells by both a paracrine and autocrine mechanism. The receptor for HGF has been identified as the product of the oncogene c-met, *raising the possibility that this gene plays a key role in facilitating cellular invasion. HGF may therefore be important not only for liver cell growth but also in metastasis. This article summarizes the current position of research on HGF, and presents both clinical and scientific evidence that strongly implicates this factor in liver regeneration and cancer invasion and metastasis.*

Discovery of hepatocyte growth factor

The appearance of novel proteins in the blood after liver resection has long been recognized. However, it was not until 1984 that the existence of a specific factor that triggered liver regeneration was defined. This factor was isolated in a partially purified form from rat plasma after partial hepatectomy by Nakamura *et al.*[1], who termed it hepatocyte growth factor (HGF). In the same year, Michalopoulos *et al.*[2] reported two serum factors related to liver regeneration, and Russell and colleagues[3] partially purified a factor from rat platelets. It was later established that these factors, named hepatopoietin A[2,4] and tumour toxic factor[5] respectively, were the same as HGF.

By 1989, HGF had been fully purified, its amino acid sequence determined and the encoding complementary DNA (cDNA) cloned[4,6,7]. HGF is derived from a single-chain precursor of 728 amino acids and processed into two peptide chains (α and β) with apparent molecular weights of 69 and 34 kDa. Its gene is located on chromosome 7, and contains 18 exons and 17 introns.

Hepatocyte growth factor and scatter factor are the same molecule

In 1985, a fibroblast-derived factor that had major effects on cell motility was described. It was named scatter factor (SF) by Stoker and Perryman[8] because it had the ability to 'scatter' tightly growing cell colonies. The factor contained heavy and light subunits with apparent molecular weights of 58 and 31 kDa. Partial amino acid sequencing revealed more than 90 per cent identity with both rat and human HGF[9,10].

The cDNAs encoding HGF and SF are the same[11] and antibodies raised against each factor recognize the other[12]. Since the factors have identical biological activities and receptors[13], most workers now refer to the molecule as HGF/SF. For convenience the factor will be referred to as HGF in this review.

Biological activity of hepatocyte growth factor

HGF has biological effects on various cell types (*Table 1*). It is recognized as the most potent stimulator of DNA synthesis in hepatocytes in primary culture. However, in contrast to normal hepatocytes, the growth of a number of hepatoma cell lines is inhibited by HGF[14,15,25]. The reason for this striking difference is not clear. Okano and colleagues[26] recently showed that the intracellular signal for HGF stimulation in these two types of cell is different; HGF induced tyrosine phosphorylation of phospholipase C_γ in normal hepatocytes but no such change was noted in hepatoma cells. HGF also regulates other functions of hepatocyte and hepatoma cells, such as acute-phase protein synthesis and α-fetoprotein production[27,28].

HGF is also a potent stimulator of cell motility. Although the canine kidney epithelial cell line MDCK is often used experimentally to demonstrate increased cell motility after treatment with HGF, a variety of other cell types also respond in a similar way, including those that are important to surgeons, such as colonic cancer cells[19], hepatoma cells and gastric adenocarcinoma cells[16]. Scattering of cell colonies is pronounced with HGF; several methods including basement membrane invasion, dissociation of carrier beads and time-lapse cinematography have been used to demonstrate that HGF increases cell motility. The increased motility may be related to changes in the cytoskeleton (for example involving F actin, myosin or vimentin[29]) or to changes of E cadherin in target cells[30].

Other properties of HGF include stimulation of haematopoietic cell growth, synergism with other cytokines[31] and 'priming' neutrophils for the oxidative response[32].

Production of hepatocyte growth factor

Many different cell types produce HGF including Kupffer cells[33], endothelial cells[33], fibroblasts[34,35], fat-storing cells in the liver[36,37], endothelial cells in the lung[38,39], HL-60 myelomonocytic cells[40] and some malignant cells, including those of lung and pancreatic carcinoma[38,41]. Expression of HGF in other normal and malignant tissues has also been reported[42,43]. Among normal tissues pancreas, small intestine, thyroid, brain and submaxillary salivary gland produce and express high levels of HGF; liver, kidney and spleen produce undetectable amounts.

The regulation of HGF production remains the subject of

intense research, but some factors that may affect this production (or messenger RNA (mRNA) expression) have been identified. 'Injurin' is a 10–13-kDa circulating protein whose level increases markedly in blood after organ injury and is a potential stimulus for HGF production[39]. HGF production and gene expression are also triggered by interleukin (IL) 1α and 1β[44], whereas both production and gene expression of HGF by fibroblasts are inhibited by transforming growth factor (TGF) β[36,45,46].

The pharmacodynamics of HGF *in vivo* are not clear. It has been reported that the factor is removed from the circulation by the liver and that both a receptor-mediated and a non-specific internalization are involved[47,48]. The kidney is responsible for HGF clearance to a limited extent.

Hepatocyte growth factor receptor

The c-*met* proto-oncogene is known to encode a receptor-like transmembrane protein; 50-kDa α and 145-kDa β subunits are generated by cleavage of a single precursor[49,50]. The β unit has both extracellular and intracellular domains; the latter has tyrosine kinase activity. The discovery of the relationship between HGF and c-*met* was first reported[13,51] in 1991. It was found that HGF could induce tyrosine phosphorylation of p145, the c-*met* proto-oncogene β subunit product. This was supported by affinity cross-linking experiments and subsequent separation of the HGF–c-*met* complex. The HGF receptor on hepatocytes was initially described as having two classes of binding affinity[52] and induces signal transduction via tyrosine phosphorylation[53] and changes in the cytosolic free Ca^{2+} level[54]. It has recently been demonstrated by Weidner *et al.*[55] that tyrosine kinase transduces all the effects of HGF on motility, growth and morphogenesis. Activation of protein kinase C, however, may inhibit c-*met*-mediated activities[56]. A wide range of cells and tissues that have been shown to express the HGF receptor or the c-*met* protein are listed in *Table 2*. Not included in *Table 2* is the receptor status of breast and breast carcinoma tissue because there is a controversy in this regard. Prat *et al.*[57], and Di Renzo and colleagues[58] failed to detect c-*met*/HGF receptor in either Northern or Western blotting analyses, or immunohistochemical studies. In contrast, Tsarfaty *et al.*[65] reported recently that both normal and malignant breast cells and tissues are c-*met*/HGF receptor positive by immunogold staining; furthermore, it was also shown that various breast cancer cells respond to HGF.

After hepatectomy blood hepatocyte growth factor level could rise as high as 100 (range 10–100) ng/ml. ELISA, enzyme-linked immunosorbent assay

Regulation of liver regeneration by hepatocyte growth factor

HGF is the most potent known stimulus for DNA synthesis by normal hepatocytes, a process that is essential for the proliferation of such cells during liver regeneration. After hepatectomy, and in a variety of liver diseases, there is a marked increase in the level of circulating HGF (up to 100 ng/ml) and increased expression of HGF mRNA in a variety of tissues (*Table 3*). It has been suggested, therefore, that HGF is a key factor for triggering liver regeneration after hepatectomy or other damage to the organ. This suggestion is strengthened by the demonstration that, after injection of labelled HGF into rats subjected to hepatectomy, there was a marked increase of HGF binding to the liver remnant[82]. Furthermore, infusion of HGF accelerated liver regeneration. Similar changes were seen in experiments with chemically induced cirrhotic liver (*Table 3*). Under these conditions, the lung may serve as the major contributor of HGF for liver regeneration[38].

In patients with fulminant hepatitis, very high concentrations of HGF are associated with a poor prognosis. The high levels reflect both the extent of the decrease of functioning hepatocyte mass and also the reduced capacity of liver to remove HGF[75].

Regulation of the regeneration of other organs by hepatocyte growth factor

There is evidence that HGF is also an important factor in kidney regeneration after surgical resection; levels of circulating HGF, mRNA for HGF and HGF receptor (c-*met*) are all increased[39,81,83] after unilateral nephrectomy. These changes may also be mediated by 'injurin'[39].

Hepatocyte growth factor and metastasis

Because of its profound effects on cell growth and motility, HGF may well be important in the growth and development of cancer metastases. Cell motility is a basic requirement for cancer cells to establish distant metastases[84] and the ability of HGF to induce motility in various cancer cells has raised understandable interest.

Overexpression of c-met *hepatocyte growth factor receptor in cancer cells*

It has been clearly shown that normal tissues, including gastrointestinal mucosa, express low or undetectable levels of mRNA for c-*met*, whereas related malignant counterparts express much higher levels of the message[62]. This receptor overexpression in malignant cells is seen in various tissues and in other transformed cells (*Table 2*). Transfection of cells that were initially negative for HGF and its receptor with c-*met* cDNA caused them to become motile and invade through the basement membrane when stimulated with HGF[85]. Transfection with the c-*met* gene also increased the tumorigenicity of malignant cells[86]. This raises the possibility that malignant cells expressing high levels of the HGF receptor are more sensitive and respond more vigorously to HGF, so becoming more motile than non-malignant cells when exposed to the factor.

It has recently been discovered that cancer cells have defective post-translational processing of the c-*met* protein. As described above, production of this protein involves synthesis of a 190-kDa precursor with subsequent cleavage to the α and β subunits that form the mature HGF receptor[54]. Activation of the mature receptor requires binding of HGF. However, in some cancer cells there is a defect in the cleavage process and the 190-kDa precursor appears in the plasma membrane. Since the precursor is itself active without ligand binding, these cells lose the control exerted by HGF and have increased motility in the absence of exogenous HGF[87].

Overexpression of the HGF receptor on malignant cells is clearly distinct from that on normal cells. Although after organ (liver or kidney) resection there is a temporary increase in HGF receptor expression on normal cells (e.g. hepatocytes), the level of expression returns to normal soon after the insult[53,88,89]. The exact underlying mechanism is not clear but this phenomenon provides evidence that normal cells and organs have the ability to control their response to HGF by reducing receptor expression, whereas malignant cells consistently overexpress the receptor and so may over-react to HGF. This may contribute to the motile and invasive nature of malignant cells.

Paracrine and autocrine regulation by hepatocyte growth factor

Levels of HGF increase in blood and other biological fluids in a number of conditions apart from liver damage. It has been shown that blood levels of HGF increase after liver resection of metastatic tumours[80]. Kaneko *et al.*[79] showed, in patients with liver metastases who had higher levels of circulating HGF than normal controls, that these levels were raised further after resection of metastatic foci in the liver. Even routine surgical operations such as cholecystectomy, colectomy and splenectomy may induce significant increases in blood HGF levels[90]. It has also been reported that patients with cancer metastases in the lung and pleura have high HGF levels in the pleural exudate[91].

Tumour cells may also produce HGF themselves; HGF or mRNA encoding this factor has been detected in fibrosarcoma[34], lung cancer[41,64,92], hepatoma[93] and pancreatic cancer[94] cells. Taken together with the high level of expression of HGF receptors on lung cancer cells[14,41,64], there exists the possibility of autocrine regulation of cancer cell motility. This is strongly supported by recent work by Rong *et al.*[86]: when cells that produced large amounts of HGF were transfected with the c-*met*/HGF receptor gene they became tumorigenic.

Angiogenesis induced by hepatocyte growth factor

The other important aspect of cancer growth and metastasis is the establishment of neovasculature by angiogenesis[95]. By inducing endothelial cell proliferation and motility, HGF can stimulate neovascularization *in vivo*[22,96,97]. This suggests that HGF, apart from increasing the invasiveness of cancer cells, may also stimulate primary and secondary tumour growth by modulating the tumour matrix. Thus, cancer cells expressing HGF receptors will become invasive and may form distant metastatic foci when exposed to HGF generated as a result of certain insults such as liver or kidney resection, or even excision of the tumour itself. In addition to this paracrine effect, autocrine production of HGF by tumour cells may also act as a positive feedback to reinforce the process.

Although HGF may be the key factor regulating tumour invasiveness, other motility agents exist, such as autocrine motility factor[98], migration-stimulating factor[99], tumour necrosis factor α[100], epidermal growth factor[101], IL-6[102], TGF-β[103], interferon γ[104], platelet-derived growth factor[105] and monocyte-derived scattering factor[106]. The regulatory mechanisms for these factors, the expression of their receptors and the interplay between them has yet to be elucidated.

The future of hepatocyte growth factor in clinical treatment

Two possible interventions aimed at reducing HGF-induced metastasis can be suggested, one aimed at lowering the responsiveness of cancer cells to HGF and the other at reducing HGF production. It has been shown that TGF-β and glucocorticoid reduce the level of mRNA for HGF[36,41] and HGF secretion[45]. Somatostatin inhibits HGF-induced growth of hepatocytes[107] but its effect on HGF-induced motility has yet to be established. An antagonist of HGF has recently been reported[108] that may compete with receptors for HGF binding without inducing adverse biological effects. Reduction of cell motility using a c-*myc* antisense oligonucleotide[109], cancer cell motility-inhibitory protein[110], extracellular matrix protein Arg–Gly–Asp sequence[111], tumour invasion-inhibiting factors[112] and other synthetic peptides[113] are other possible lines of approach for the future.

In conclusion, HGF is a factor that regulates growth, motility and morphogenesis. It plays key roles in the regeneration of liver and other organs and also in cancer metastasis. A further understanding of its role will have implications for clinical practice.

Acid gastro-oesophageal reflux occurs when the lower oesophageal sphincter is incompetent, but oesophagitis caused by reflux of duodenal content implies incompetence of both the pyloric and gastro-oesophageal sphincters. The term 'alkaline' reflux oesophagitis was coined long before objective analysis was made of bile in the stomach and oesophagus, and well before pH monitoring was introduced. Surgical procedures to divert bile from the stomach and oesophagus were developed on a clinical basis and gave encouraging results in the management of peptic oesophageal stricture. Alkaline oesophagitis is well recognized after gastric surgery and the entity 'primary pathological duodenogastric reflux', although contested by some, attracts growing support. Recent evidence suggests that the complications of Barrett's oesophagus may be related to duodenogastro-oesophageal reflux. Probes designed to measure gastric and oesophageal bile salts have recently been developed and may give more information in the future.

Gastro-oesophageal reflux disease (GORD) has become a common condition in most Westernized societies. The role that gastric acid plays in its pathogenesis is well established[1] and forms the basis for medical therapy. Many patients, however, fail to respond to potent acid-suppressing drugs such as omeprazole. This drug heals oesophagitis in 67–92 per cent of patients overall and, although successful for the lower grades of oesophagitis, will heal only 48–62 per cent of those with grade IV disease[2]. The reason why such marked acid suppression fails to heal all cases needs to be explained; one possible reason for failure is that the reflux contains duodenal contents that are not suppressed by omeprazole. Furthermore, oesophagitis is seen in patients with atrophic gastritis, pernicious anaemia and following total gastrectomy[3–5], indicating that the pathology may also be caused by 'acid-free' reflux. These facts led to the concept of 'alkaline' reflux oesophagitis which, although debated for decades, is still not completely understood or even accepted. Alkaline flushes (pH > 7) demonstrated in the oesophagus by ambulatory pH monitoring may indicate exposure to duodenal contents, namely bile and pancreatic juice, both of which potentially cause mucosal damage. Pellegrini *et al.*[6] measured pH values >7 in the oesophagus and recognized three kinds of abnormal gastro-oesophageal reflux: acid, mixed acid–alkaline and alkaline. Alkaline gastritis, a better accepted entity than alkaline oesophagitis, is a common complication after gastric surgery. Blum *et al.*[7] questioned the relevance of primary duodenogastric reflux, and considered alkaline gastro-oesophageal reflux to be an uncommon condition. Gowen[8], however, identified 42 patients who met the criteria for primary enterogastric reflux gastritis and oesophagitis. All had a constant burning epigastric pain that was worse after meals and unrelieved by antacids or diet, endoscopic evidence of a gastric bile pool, endoscopic biopsy proof of gastritis and oesophagitis, and hypochlorhydria.

Crumplin *et al.*[9] also showed that there was an increase in total bile salts in the gastric aspirate from patients with sliding hiatal hernia and reflux stricture. Using these same criteria in another study, ten patients with primary pyloric incompetence and complicated alkaline oesophagitis were treated by vagotomy and Roux-en-Y diversion with good results[10].

Pathophysiology of oesophageal mucosal damage

In 1833, Beaumont reported observations on his patient Alexis St Martin and noted that 'bile was seldom found in the stomach except under special circumstances'[11]. Du Plessis[12] in 1965 and Capper[13] in 1967 presented evidence suggesting that duodenogastric reflux played a role in the pathogenesis of gastric ulcer and gastritis. Teorell[14] reported on the effect that bile had on the permeability of the gastric mucosa to hydrogen ions (H^+), and Davenport[15] showed that bile could break down the gastric mucosal barrier. Lillemoe *et al.*[16] demonstrated that, in the normal state, a mucosal barrier exists in the oesophagus in much the same way as had been shown previously in the stomach. Furthermore, it was shown in a rabbit model that bile was actually absorbed during disruption of this oesophageal mucosal barrier and that the net flux of H^+ through the rabbit oesophageal wall increased with increasing concentrations of taurodeoxycholate[16,17]. Oesophageal mucosal resistance, which prevents injury from noxious substances, has several components. Oesophageal motility and salivary flow assist with oesophageal clearance[18], while mucosal tight junctions, intercellular matrix and endogenous leukotrienes act as diffusion barriers[19]. The cellular contribution to protection comprises resistant cell membranes, cytoplasmic proteins, bicarbonate transport mechanisms and Na^+–H^+ exchange mechanisms to maintain intraoesophageal pH[19]. In the experimental rabbit model, luminal acid does damage the oesophageal mucosa, but high concentrations (300 mmol/l HCl) are needed to exert even minor influences on mucosal integrity[20]. The addition of taurocholate, pepsin and lysolecithin, however, causes severe mucosal damage even with lower rates of H^+ diffusion[17]. Erosive oesophagitis can be produced in dog models with bile, pancreatic juice or a mixture of the two[21–23]. These observations led to laboratory confirmation of the deleterious effect of bile on the oesophageal mucosa of monkeys. Gillison *et al.*[24] showed that acid reflux alone rarely caused oesophagitis, but a mixture of bile and acid produced serious oesophagitis and stricture formation. More recently, Safaie-Shirazi *et al.*[25] showed that H^+ flux through the oesophageal wall was minimal with acid reflux but increased fivefold when bile acids were added to the reflux in dogs and humans.

Measurements in humans

Whether bile acids or pancreatic juice play a causative role in the development of oesophagitis in the human is controversial[23]. Most of the evidence supporting oesophageal mucosal injury by bile came from animal experiments. But do duodenal contents, be they bile, pancreatic juice or a mixture,

0007-1323/93/111374-03 © 1993 Butterworth-Heinemann Ltd

cause oesophagitis in humans? Following total gastrectomy and oesophagojejunal anastomosis, severe oesophagitis results clinically and in the experimental model[3]. Bile diversion affer total gastrectomy with Roux-en-Y reconstruction prevents oesophagitis and is currently a standard technique. Bile diversion procedures were used clinically to treat severe oesophagitis and stricture formation long before experimental studies investigated the role of bile in the pathogenesis of oesophagitis. Good results after these operations without prior laboratory proof of alkaline reflux were reported by independent investigators[26,27].

The presence of bile in the oesophagus of patients with oesophagitis but with an intact stomach and pylorus is not well documented. A role for bile in the pathogenesis of oesophagitis seemed probable when Gillison *et al.*[28] reported duodenogastric reflux in 52 of 59 patients with heartburn and in only four of 21 controls. Kay and Showalter[29] also found increased bile concentrations in the stomach of about half of patients with peptic oesophagitis and peptic oesophageal stricture. Increased concentrations of bile have also been detected in the gastric aspirate of patients with oesophagitis[30].

Duodenogastric reflux and complicated Barrett's oesophagus

In 1977, Bremner[31] postulated that bile reflux was involved in the pathogenesis of Barrett's ulceration, and in 1981 Bremner and Hamilton[32] reported increased levels of bile acids in the gastric juice of some patients with Barrett's oesophagus. The columnar lining of the oesophagus develops in the presence of severe acid gastro-oesophageal reflux and it was suggested that acid reflux alone was unlikely to cause ulceration or stricture formation. In 1985, Bremner and Hamilton[33] reported an increased gastric bile acid content in patients with Barrett's stricture. In 1988, Gillen *et al.*[34] showed that postprandial gastric bile acid concentrations were significantly greater in patients with complications associated with Barrett's oesophagus than in those with uncomplicated disease, giving support to Bremner's hypothesis. Using hepatobiliary scanning techniques, Waring *et al.*[35] demonstrated duodenogastric reflux in six of 13 patients with Barrett's oesophagus and in only two of 19 controls. Attwood *et al.*[36] in 1989 again showed a strong relationship between the presence of duodenogastric reflux and the occurrence of complications associated with Barrett's oesophagus. All of these experiments provided indirect evidence implicating bile or duodenal contents in the pathogenesis of the complications of Barrett's oesophagus.

Bile salts in the oesophagus

The demonstration of increased levels of bile salts in the stomachs of patients with symptomatic gastro-oesophageal reflux strongly suggests that bile refluxes into the oesophagus of these patients. Gotley *et al.*[30] performed continuous aspiration of the oesophagus in control subjects and patients with oesophagitis; conjugated bile acids were detected in the oesophagus of most patients with oesophagitis and this reflux occurred mostly during supine resting periods. Johnsson *et al.*[37] also sampled oesophageal contents during ambulatory 24-h pH monitoring in 18 patients with oesophagitis; all but one had bile salts in the oesophagus. The concentration of bile salts was low, however, and similar to that found in the gastric juice of the ten normal controls. In similar aspiration studies performed by Mittal *et al.*[38] only small amounts of bile were detected in the oesophagus. Duodenal contents detected in the oesophagus in small concentrations may be of no consequence at all; Gotley *et al.*[39] found bile in sufficient concentrations to cause mucosal damage in only 2 per cent of oesophageal aspirates in patients with GORD. Gotley *et al.*[30] also pointed out the fallacies of using the 3α-hydroxysteroid dehydrogenase enzymatic technique for analysis of bile acids; they used a sensitive and specific liquid chromatography method to assay six of the most prevalent bile acid conjugates. An important finding of their study is that gastric juice containing potentially cytotoxic levels of bile acids frequently has a pH $<3{\cdot}5$, which would be registered as acid reflux. Very recently, Stein *et al.*[40] used the new technique of combined ambulatory oesophageal aspiration and pH monitoring to demonstrate an increase in the presence of bile acids in the oesophagus of patients with erosive oesophagitis and Barrett's oesophagus. Interestingly, this increase was again shown to be maximal during supine periods, and there was a significant correlation between bile acid concentration in the aspirate and the proportion of time that a pH >7 was observed on the ambulatory oesophageal pH monitor. Trypsin was seldom found in the aspirates studied by Gotley *et al.*[41], but pepsin concentration was high in patients with stricture and Barrett's oesophagus; it was concluded that pepsin in an acid medium may be responsible for the oesophageal damage.

Bremner *et al.*[42] also showed that the greatest prevalence of mucosal damage to the oesophagus occurred in patients with increased oesophageal exposure to a pH of 0–2, corresponding to the known pK_a of pepsin, and in those with an increased exposure in the pH 7–8 range. Pepsin, therefore, causes mucosal damage in an acid environment and trypsin is destructive at pH 5–8. Alkalinization of the stomach by effective antacid therapy in patients with gastro-oesophageal reflux could theoretically be harmful by allowing reflux of trypsin in an alkaline environment.

Duodenogastric reflux and cancer

Yasui *et al.*[43] recently compared results of 24-h gastric and oesophageal pH monitoring in 17 patients with early gastric cancer and 42 with Barrett's oesophagus; it was found that in complicated Barrett's disease and early gastric cancer pathological duodenogastric reflux was present. Such reflux was, however, inferred from recordings of pH$>$7.

Bile is known to be associated with gastrointestinal carcinogenesis, an effect that is not confined to the stomach or oesophagus. Nagengast[44] presented evidence to suggest that bile promotes carcinogenesis in the colon. As has already been discussed, there is strong evidence that ulceration and stricture formation in Barrett's oesophagus may be related to alkaline reflux oesophagitis. Is it possible that the same irritants from duodenogastric reflux are associated with the development of adenocarcinoma in the columnar-lined oesophagus? There is experimental evidence in the rat model to show that adenocarcinoma may develop in the presence of duodeno-oesophageal reflux[45,46].

Improved techniques are being used to detect duodenogastric reflux. Ambulatory gastric pH monitoring has shown an increasing prevalence of such reflux in symptomatic patients that was not seen with isotope scanning techniques using di-isopropyl iminodiacetic acid[47]. Using discriminate analysis, a composite scoring system with 16 variables of circadian gastric pH recording was shown to differentiate patients with known duodenogastric reflux disease from normal volunteers[48]. Recording pH, however, is an indirect measurement that assumes duodenogastric reflux.

The future

An intraoesophageal probe that can continuously measure ^{99m}Tc-labelled bile reflux into the stomach or oesophagus has been developed. The technique is, however, qualitative and will not measure concentration[49]. More recently, Bechi *et al.*[50] reported use of a fibreoptic sensor for ambulatory assessment of enterogastric and non-acid gastro-oesophageal reflux. The basic working principle in this apparatus is that an absorption peak centred around 453 nm in the gastric or oesophageal lumen automatically implies the presence of bile reflux. If this apparatus proves to be a reliable tool for measuring bile in the gastrointestinal tract, the mysteries of alkaline reflux oesophagitis could be resolved.

Paper accepted 7 June 1993

Association of Surgeons of Great Britain and Ireland

A meeting of the Association of Surgeons of Great Britain and Ireland took place in Birmingham on 14–16 April 1993. The President of the Association, Miss Averil O. Mansfield, was in the chair.

Br. J. Surg. 1993, Vol. 80, November, 1377–1378

Organization of general surgical services in Britain: strategic planning of workload and manpower

A. E. B. Giddings

Working Party, Council of the Association of Surgeons of Great Britain and Ireland, c/o The Royal College of Surgeons of England, 35–43 Lincoln's Inn Fields, London WC2A 3PN, UK

Correspondence to: Mr A. E. B. Giddings

At the 1993 annual general meeting of the Association of Surgeons of Great Britain and Ireland there was a vigorous debate on the number of consultants required to meet the future needs of general surgery. This deliberation continued the discussions of previous meetings in which detailed studies of surgical workload were reported[1]. That workload related to the provision of acute services and it was recognized that acute hospitals must be large enough to provide a comprehensive range of specialist skills[2]. There is already evidence from the Department of Health circular *Achieving a Balance*[3] that consultant numbers in the UK need to be increased. Analysis of service load, the number of acute sites and the need for concentration of specialist skills suggests that a new initiative is urgently required to increase markedly the number of consultant general surgeons in Britain.

At this year's meeting Mr Peter Doyle, a senior registrar in public health medicine, spoke on existing surgical manpower resources and the effects of the 'new deal'[4] on junior doctors' hours. The new training responsibilities for consultants and the new role of postgraduate deans were reported by Mr John Temple, speaking as a surgeon and postgraduate dean[5]. Mr Robert Baigrie of the Association of Surgeons in Training also described the problems faced by surgical trainees and how they might be solved within the constraints of the new deal.

Peter Doyle's analysis of general surgical manpower using the latest Department of Health Medical Manpower Census figures from 1991 shows that at the start of this decade there were approximately 1000 consultant general surgeons covering over 300 acute service sites in England and Wales. These general surgeons serve a population of more than 50 million, giving a ratio[6] of approximately 1:50000. They include specialists in vascular surgery, renal transplantation and other subspecialties, most of whom have continued involvement in providing emergency general surgical cover. Subspecialty cover is even more thinly spread: for example, in vascular surgery there is only one consultant for every 211000 individuals[7].

There has been a gradual but slow increase in consultant numbers in recent years: at best 3 per cent and at worst 1 per cent per year. If the best rate of expansion is maintained, there will be 1408 general surgical consultants by the year 2000, but only 1180 if expansion is at a rate of 1 per cent. Even 3 per cent would fall short of the target identified by the Association to supply one general surgeon for every 30000 population; this ratio is presently achieved only in Northern Ireland and parts of Scotland. The population of England and Wales is projected to reach 53 million by the year 2000. It would then require more than 1700 general surgeons to reach the target, an increase of 66 per cent over current levels. Such an expansion would bring Britain more closely into line with several other European countries.

The current trends are inadequate to meet the requirements of the new deal on junior doctors' hours or the challenges of modern postgraduate training. The new deal for junior hospital doctors has established a maximum emergency commitment of 1 in 5 as desirable if a 1 in 4 service with internal cover is to be applied to all grades of staff. This must be so if high standards are to be preserved. Three levels of competence are required for a modern emergency service in a hard-pressed specialty[8]: house surgeon, intermediate grade and consultant. The intermediate-grade doctor may be a registrar, senior registrar or an experienced senior house officer who is defined by the national safety-net agreement[3] as one who has spent a minimum of 1 year after registration in surgery in general. Consultants who are not recognized as trainers would need the support of a career-grade person such as a staff-grade doctor. Assuming a 1 in 5 rota and taking account of the requirements of the central Joint Planning Advisory Committee and the reduced length of training, the present intermediate-grade surgical manpower in the UK could cover only 165 acute sites, that is just over half those currently providing acute services. These are powerful additional forces to promote the merging of adjacent units and the end of split-site working.

John Temple also pointed out that the reduced hours of the new deal will lead to an increase in the workload for both trainees and consultants, and it will be vital to provide protected time for education during normal working hours. There will be fewer trainees, and not all consultants will be trainers. Standards of training will be defined and required by contracts, and time will be needed for formative assessment and for certification of the competence of trainees. Shorter structured training and the need for continuing medical education (continuing professional development) will demand more consultant time. That demand will be met only by an expansion in the number of consultants. Such expansion is fully supported by the Association of Surgeons in Training, whose members remain overexperienced and undertrained. Junior staff saw expansion in consultant numbers as essential; they gave no support to the concept of service provision by a doctor of subconsultant grade.

There are also the issues of specialist registration in the European Community. The suggestion has been made that all experienced registrars and senior registrars should receive independent specialist status to achieve harmonization within Europe, but even this development would hardly approach the desired ratio. It would also be likely to degrade the high standards of consultant practice in the UK. Shorter structured training could, however, make a useful contribution to consultant manpower by accelerating the addition of fully trained surgeons to the permanent workforce. Such a solution would reduce the trainees' contribution to the service at the intermediate grade and make the rationalization of services and acute sites even more necessary.

Since the meeting of the Association, Council has considered and responded to the Calman Report[9], pointing out that these

0007-1323/93/111377-02 © 1993 Butterworth–Heinemann Ltd

new proposals will also demand more consultants. The Association believes that the Calman objectives can be achieved only by sustained political determination and substantial new money. All these issues – manpower planning, postgraduate training, hours of work and the distribution of specialist services – have come together to support the *ten principles* developed and agreed by the Association. These principles concern strategic planning of workload and manpower in general surgery, excluding urology:

1. The Association is committed to improving the quality of patient care by moving towards a consultant-based service before the year 2000. This objective can be achieved only through a substantial increase in the number of consultant surgeons.
2. The Association reaffirms the principle that all surgical patients should remain the responsibility of a named consultant duly appointed by a properly constituted advisory appointments committee. Only consultants should be responsible for appropriate delegation of work to more junior staff.
3. A general surgeon is defined as one who participates in the emergency rota for general surgery in addition to his or her subspecialty interest.
4. The Association confirms that the desirable ratio of consultant general surgeons to catchment population is 1:30 000 (current mean 1:50 000)[6]. Such a ratio would lead to an improvement in the quality of care for patients undergoing emergency, urgent and elective procedures. It would also facilitate the training of junior doctors.
5. The Association fully supports recommendations by the National Confidential Enquiry into Peri-Operative Deaths that emergency surgery should be carried out during the day whenever possible, that this requires the provision of appropriate facilities and that, when the surgeon is 'on take' for emergencies, he or she should have no other responsibilities likely to delay treatment of patients.
6. The Association recommends that the job plan of a full-time or maximum part-time consultant in general surgery in the National Health Service should include one or two outpatient sessions (1–2 notional half-days), of which some may take place outside base hospitals, and three or four operating sessions (3–4 notional half-days) per week[10]. These sessions should be supported by an adequate number of beds and other facilities, bearing in mind emergencies, the consultant's special interest and the age structure of the population.
7. Service contracts based on intermediate (or hernia) equivalents should be sensitive to case mix and the needs of trainees[1]. An appreciable proportion of a consultant's operating time will be spent on the training of junior staff, which will become more structured and intensive. Employing authorities must recognize and budget for this crucial activity. Individual service contracts should take account of the importance of funded study leave in continuing medical education (continuing professional development) and allow for annual and professional leave.
8. A consultant rota commitment for emergency admissions in general surgery should not normally exceed a mean of 1 in 5. Onerous emergency commitments may be recognized by appropriate time off.
9. The Association regards continuing education by and for consultants as mandatory and supports its inclusion as a contractual obligation. At least 1 notional half-day session per week is required for continuing education.
10. The Association believes that the provision of efficient general surgery requires the concentration of acute services on one site serving a population[2] of approximately 300 000. This figure may have to be modified in areas with a widely dispersed population. The ideal acute hospital requires: (1) ten general surgeons with appropriate subspecialty interests and adequate junior staff support to facilitate cover; (2) an intensive care unit with sufficient beds and trained staff; and (3) facilities for the prompt treatment of surgical emergencies, with theatres and support services available on a 24-h basis and access to other specialist services.

These ten principles have been extensively discussed and refined by the Association and approved at the annual general meeting. They provide a clear direction for the development of general surgical services for this decade and the next generation.

1379–1380

Eye protection for the vascular surgeon

Contamination occurring during vascular surgery was studied prospectively using a surgical mask incorporating a Splashguard visor. Over a 16-week period 78 vascular procedures were included; 44 were of <2 h duration and 34 were of $\geqslant 2$ h. Contamination on both mask and visor from blood spots was recorded at the end of each procedure. Overall, 51 per cent of principal surgeons' visors were contaminated, with contamination of the mask itself in 32 per cent. When two surgeons were operating the contamination rate for the second was also high: 36 per cent for the visor and 42 per cent for the mask. Assistants had a contamination rate of 36 per cent for the visor and 13 per cent for the mask. The lowest rate of contamination occurred for the visor and mask of the scrub nurse, 10 and 4 per cent respectively. For emergency procedures the duration of operation had no influence on the frequency of contamination. However, for the principal surgeon elective operations of <2 h duration were less likely to involve contamination than those of $\geqslant 2$ h ($\mathrm{P}<0{\cdot}035$). Blood contamination of visors and masks is common in vascular surgery but rarely appreciated by the surgeon. Routine eye protection should be considered in vascular surgery, in particular for emergency and prolonged elective procedures.

D. C. Berridge, T. A. Lees, J. Chamberlain and N. A. G. Jones

Department of Vascular Surgery, Freeman Hospital, High Heaton, Newcastle upon Tyne NE7 7DN, UK

Correspondence to:
Mr D. C. Berridge

Vascular surgeons are inevitably at risk[1] from hepatitis B and human immunodeficiency virus (HIV). Although for high-risk patients full precautions are advisable[2], the level of protection that should be used for other patients is less clear. Double gloving reduces the number of glove punctures[3] and probably should be used in all major thoracic, abdominal and femoropopliteal reconstructions. For femorotibial or femoroperoneal reconstruction double gloving may impair the fine touch necessary for dealing with these smaller vessels.

Eye protection for orthopaedic[4,5], otorhinolaryngology[6] and maxillofacial[7] surgeons has recently been advocated, particularly when power tools are in use. However, scant regard has been paid to the potential conjunctival route of transmission in vascular surgery. Brealey and Buist[8] studied a consecutive series of 257 operations of which 25 were arterial in nature. Visors or protective glasses were not worn but the number of spots contaminating ordinary spectacles was noted. Of the 25 arterial procedures, 11 caused contamination of spectacles, but no reference was made to the type of arterial operation performed, or to the contamination of the assistant or scrub nurse. Furthermore, these authors stated that 'conventional spectacles provide only partial protection: several of the blood splashes were on the inner surfaces of our lenses.' The present study examined the contamination occurring during major vascular surgery, using a surgical mask incorporating a Splashguard visor (Universal Hospital Supplies, London, UK).

Patients and methods

For 78 consecutive vascular operations performed over a 16-week period, the surgeon(s), first assistant and scrub nurse were requested to wear a Splashguard visor mask throughout the entire procedure. At the end of the operation the mask and clear plastic visor were graded separately for macroscopic contamination with blood splashes. The total number of separate splashes was counted and any major contamination recorded. A record was also kept of elective and emergency cases, the nature of the operation performed and its duration. Results are expressed as mean(s.d.) or median (range) as appropriate. Statistical analysis was performed using the χ^2 test.

Results

Seventy-eight consecutive vascular procedures (50 elective, 28 emergency) performed over a 16-week period were studied. Forty-four procedures were of <2 h duration, mean(s.d.) 76(34) min, and 34 were of $\geqslant 2$ h, mean(s.d.) 188(61) min. Procedures ranged from ruptured aortic aneurysm repair to amputation and vein surgery (*Table 1*).

Contamination with blood spots on both mask and visor, as recorded at the end of each procedure, varied considerably according to the role of the wearer. Of principal surgeons' visors 51 per cent were contaminated (median number of spots 6 (range 1–35)), with contamination of the mask itself in 32 per cent (median number 4 (range 1–40)). For a second operating surgeon the contamination rate was also high, 36 and 42 per cent respectively. Contamination rates decreased with increasing distance from the site of surgery. The contamination rate for the assistant was 36 per cent for the visor but only 13 per cent

Table 1 *Procedures performed*

	Elective	Emergency
Carotid endarterectomy	1	0
Abdominal aortic aneurysm repair	9	6
Axillobifemoral graft insertion	2	2
Femoral false aneurysm repair	2	2
Profundoplasty	2	0
Femoropopliteal or femorodistal bypass	12	3
Iliofemoral crossover bypass	1	1
Iliopopliteal bypass	2	0
Iliac–superior mesenteric artery bypass	1	0
Femoral embolectomy	1	8
Femoral artery or vein repair	0	2
Infected aortobifemoral graft excision	0	1
Supraclavicular neck dissection	1	0
Exploration of artery	2	1
Varicose vein surgery	8	0
Above- or below-knee amputation	3	0
Other	3	2
Total	50	28

0007-1323/93/111379–02 © 1993 Butterworth–Heinemann Ltd

Table 2 *Contamination of visors and masks*

	Visor		Mask	
	Contaminated (%)	Median (range) no. of splashes	Contaminated (%)	Median (range) no. of splashes
Principal surgeon	51	6 (1–35)	32	4 (1–40)
Second surgeon	36	3 (2–34)	42	1 (1–6)
Assistant	36	3 (1–12)	13	3 (1–3)
Scrub nurse	10	2 (1–4)	4	2 (1–3)

for the mask. The scrub nurse showed the lowest rate of contamination, blood affecting the visor in 10 per cent of cases and the mask in 4 per cent (*Table 2*).

There were three instances of major contamination; in all cases a power saw was in use for bone division as part of amputation. With the exception of these three cases, most contamination was not noticed by the surgeon during the course of the procedure.

For emergency cases the duration of the operation had no influence on the frequency of contamination. However, for the principal surgeon elective operations of <2 h duration were less likely to involve contamination than those of $\geqslant 2$ h (34 *versus* 65 per cent, $P<0.035$).

Discussion

Although the risk to healthcare personnel of contracting hepatitis B has been recognized for many years, surgeons have been slow in adopting preventive measures in surgical practice. The availability of hepatitis B immunization has reduced the risk of infection but, despite this, uptake of immunization among vascular surgeons is not universal[1]. Increased awareness of the risk of HIV infection, however, has accelerated progress in the protection of theatre personnel in general. Extra precautions can obviously be adopted for at-risk cases – patients with known infection or those belonging to high-risk groups. However, there will always be patients who, possibly unknown to themselves, carry the HIV and/or hepatitis B virus. Also, for patients who test negative for HIV infection, it has been suggested that seroconversion can be prolonged, possibly as late[9] as 36 months.

Some surgeons may feel that their normal spectacles offer sufficient protection but contamination may occur on the inner aspect of the lenses[8]. Furthermore, Bell and Clement[5] demonstrated a 5 per cent rate of contamination of protective side flaps. Conjunctival transmission of hepatitis B can occur and HIV may also be transmitted via this route. While Seale[10] has suggested that it may require only one viral particle of HIV to allow transmission, making blood splashes to the conjunctiva a real problem[11,12], the actual risk is small. In a survey of 938 healthcare workers known to have incurred parenteral or mucous membrane exposure to blood or other body fluid from patients with acquired immune deficiency syndrome or related illnesses, only two were found to be seropositive. One had been contaminated with a colonic biopsy needle and the other by a deep, hollow needlestick injury[13]. As far as the present study is concerned, it must also be recognized that the surface area of the conjunctiva is much less than that of the visor; contamination of the latter does not necessarily equate with eye contamination.

This study has demonstrated that blood contamination of visors and masks is common during vascular surgery. Blood splashes occur particularly in emergencies and in elective procedures lasting 2 h or more. Although the risk of serious infection currently appears to be small, over a surgical career the cumulative risk may be significant. The authors suggest that eye protection should be seriously considered for all types of vascular surgery but, in particular, for emergencies and prolonged elective operations.

Genetic linkage analysis applied to unaffected women from families with breast cancer can discriminate high- from low-risk individuals

Up to 20 per cent of cases of breast cancer diagnosed in women under the age of 45 years may be caused by an autosomal dominant gene. A present difficulty is differentiation of mutation carriers from non-mutation carriers in high-risk families. Genetic linkage analysis has been used to localize a susceptibility gene (BRCA1) *on chromosome 17q12-21 between markers 42D6 and MFD188, a region 5–10 million base pairs in length. Odds in favour of linkage to this region were greater than 100 000:1 in 15 families with breast cancer. In eight families in which the probability of linkage was above 75* (*range 79·2–99·9*) *per cent, 19 women were identified who were at high lifetime risk of breast cancer* (*range 80·6–87·2 per cent*) *and 37 whose risk was similar to that for the general population* (*range 9·8–16·4 per cent*). *Genetic risk prediction of this kind may enable high-risk screening clinic resources to be concentrated on those most likely to benefit.*

A major risk factor for breast cancer is a positive family history of breast malignancy, especially when affected relatives have included those of young age with bilateral disease[1–6]. A common feature of heritable breast cancer is the occurrence of families in which malignancy is diagnosed early in life, although in these the disease is not always distributed according to strict mendelian principles. Genetic epidemiological studies (segregation analysis), however, consistently suggest that these pedigrees do not simply represent chance clusters of cancer. They frequently reflect the phenotypic effect of single autosomal dominant genes that are carried in 1–6 of every 1000 individuals and which give a greater than 80 per cent lifetime risk of breast cancer with a 40 per cent risk before the age of 50 years[7–9].

These epidemiological features of familial breast cancer suggest that, in the catchment area of the Edinburgh Breast Unit (population of south-east Scotland approximately 1 million), 750 women between 30 and 50 years of age will be carriers of a major breast cancer susceptibility gene. Approximately 15 breast cancers per annum would occur in this high-risk group, which corresponds to nearly 20 per cent of the total diagnoses in women between the ages of 30 and 50 years (*Table 1*)[9]. Such a cohort of young women might be a cost-effective group for breast screening with the aim of detecting malignancy early and thereby reducing morbidity and mortality rates from breast cancer. Screening on the basis of family history alone would fail to target many gene carriers since some would be unaware of their family history and others would have inherited the gene through the paternal line or through female ancestors who did not express the disease phenotype. Still others might exhibit *de novo* germ line mutation. Some individuals would have a strong family history of breast cancer simply by chance and without genetic susceptibility. This phenomenon was recognized by Paget[10] over 100 years ago. Furthermore, according to mendelian laws of inheritance, half of the daughters of a mutation-carrying parent would not have inherited the trait and would be at no greater risk than the population as a whole.

It therefore appears unlikely that selection of patients for high-risk clinics based simply on a positive family history would identify susceptible individuals with great specificity or sensitivity. The sites of mutations responsible for familial breast cancer need to be determined and then women who carry them identified. Recent work has centred on the tumour suppressor gene *BRCA1*.

BRCA1 is located[11–13] on chromosome 17q12-21. Genetic linkage analysis, using polymorphic markers in this region to type more than 200 families, has determined that the odds in favour of a breast cancer susceptibility gene existing in close proximity to these markers are many millions to one[14]. This consortium analysis has calculated that *BRCA1* gene mutation is likely to be implicated in the aetiology of malignancy in approximately 50 per cent of families with breast cancer.

In Edinburgh, a total of 206 individuals in 15 families containing between three and nine patients with breast cancer were typed at markers 42D6 and MFD188. Typing was achieved by means of polymerase chain reaction amplification of polymorphic fragments and acrylamide gel electrophoresis. A maximal lod score of +5·62 was obtained on the basis of hypothetical *BRCA1* gene location (θ) 2·5 cM from marker 42D6. The odds in favour of a gene existing at this site were greater than 100 000:1. Recombination data in *BRCA1*-linked pedigrees suggested that 42D6 and MFD188 were probable flanking markers, locating *BRCA1* to a region 5–10 million base pairs in length[15].

Table 1 *Contribution of a major heritable breast cancer gene to breast cancer in general in women aged 30–50 years in south-east Scotland*

	Gene carriers	Non-gene carriers
No. of individuals	750	125 000
Disease penetrance (% per annum)	2	0·05
No. of breast cancers per annum	15	70
Percentage of breast cancers	20	80
Screening viability	Yes	No

Knowledge of prior probability of *BRCA1* linkage[14] and calculation of lod scores in each family[15] might enable the lifetime risk of breast cancer to be reassessed in female relatives as yet unaffected by the disease. This would be the first step in the process of identification of probable gene carriers, a cohort that might benefit from regular breast screening at an earlier age.

Patients and methods

Fifteen Edinburgh pedigrees each containing at least three patients with breast cancer in blood lineage had been previously typed[15] at markers 42D6 and MFD188. Dates of birth and death and cause of death were confirmed from the records of the Registrar General of Scotland. Where possible, malignant diagnosis was confirmed from hospital sources. Lod scores at 42D6 and MFD188 were calculated for each pedigree on the basis of a genetic model for familial breast cancer produced from a large British epidemiological study[9]. From maximal lod scores, conditional probability of linkage to *BRCA1* was determined for each family according to the equation:

$$x = \frac{100y}{y+1}$$

where x is the percentage conditional probability of linkage and y the inverse $\log_{10}$ maximal lod score. Heterogeneity analysis of lod scores in 214 breast cancer pedigrees (157 site-specific breast cancer families, 57 breast–ovarian cancer subtype families) suggested[14] that up to 50 per cent of site-specific breast cancer families and more than 75 per cent of breast–ovarian cancer subtype families are likely to be linked to *BRCA1*. These values are prior probabilities of linkage to *BRCA1* and are not prejudiced by marker data in any single pedigree.

Bayesian principles of genetics combine prior and conditional probability to calculate final (or posterior) probability[16] according to the equation:

Posterior probability in favour
= (prior probability in favour × conditional probability in favour)
÷ [(prior probability in favour × conditional probability in favour)
+ (prior probability against × conditional probability against)]

Posterior probability in favour of linkage to *BRCA1* was calculated in the 15 families with breast cancer subjected to linkage analysis with *BRCA1* flanking markers. Ten pedigrees were site-specific breast cancer families and five were of the breast–ovarian cancer subtype (which required at least one patient with ovarian cancer in the lineage for classification).

In a single hypothetical pedigree, posterior probability of linkage of 75 per cent indicates that the probability that a mutant susceptibility gene close to the markers that flank *BRCA1* has caused disease in the family is three times more likely than not. Arbitrarily in this study, pedigrees with posterior probability of linkage greater than 75 per cent were considered as probably linked to *BRCA1*. The probability that unaffected women in these 'probably linked' families were carriers of the *BRCA1* mutation was calculated on the basis of *BRCA1* flanking marker data. The lifetime risk of breast cancer in these women was estimated according to the probable presence or absence of *BRCA1* mutation.

Table 2 *Maximal lod score at 42D6 or MFD188 markers, and conditional and posterior probabilities of linkage in eight families with breast cancer with probable* BRCA1 *linkage*

Results

Maximal lod score at 42D6 or MFD188, conditional probability of linkage to *BRCA1* and posterior probability of linkage for each of eight breast cancer pedigrees showing probable *BRCA1* linkage are recorded in *Table 2*. *Figure 1* illustrates posterior probability of linkage in all 15 families divided into breast–ovarian and breast cancer (site-specific) families. *Table 3* records the numbers and ages of women unaffected by breast cancer and the percentage probability in favour of *BRCA1* carrier status. Lifetime risks of breast cancer, calculated on the basis of marker data, are also shown.

For demonstration, the methodology employed in calculating the likelihood of *BRCA1* carrier status and lifetime risk of breast cancer in unaffected women in a single pedigree is illustrated below.

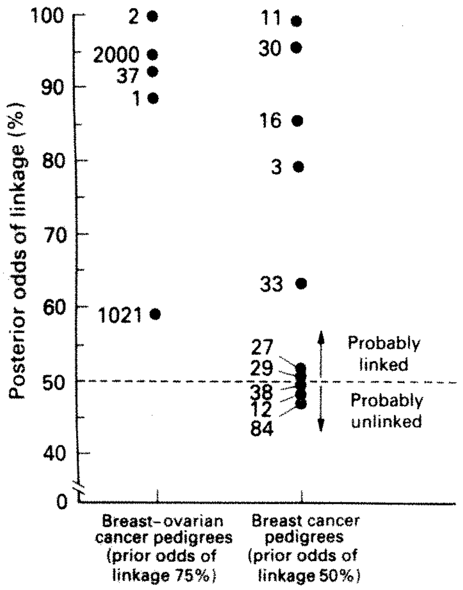

Figure 1 *Posterior probability of linkage in 15 Edinburgh families identified by pedigree number, calculated on the basis of prior odds and conditional odds from 17q marker data*

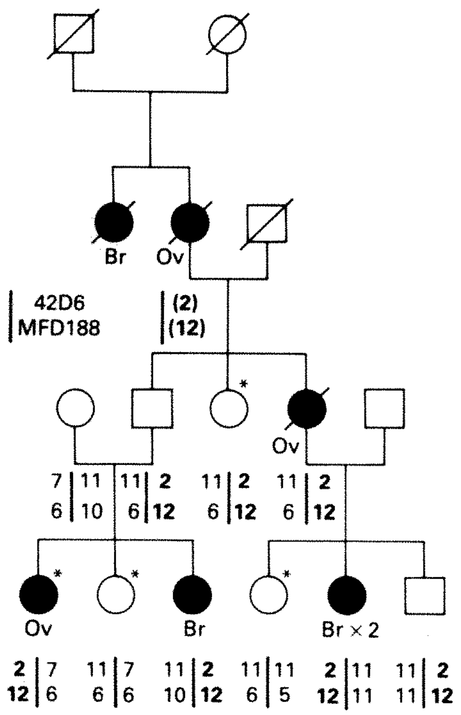

Figure 2 *Edinburgh pedigree 2000 with haplotypes at markers 42D6 and MFD188. Br, unilateral breast cancer; Br × 2, bilateral breast cancer; Ov, ovarian cancer. *Women alive, unaffected by breast cancer and typed at 17q markers*

Pedigree 2000 with haplotypes at 42D6 and MFD188 is illustrated in *Figure 2*. This breast–ovarian cancer subtype family has prior probability of linkage to *BRCA1* of 75 per cent[14]. A maximal lod score of +0·77 was calculated using marker MFD188 at $\theta = 1 \times 10^{-6}$. The percentage conditional probability of linkage (x) is:

$$x = \frac{100y}{y+1}$$

$$= \frac{100(\text{inverse}\log_{10}0{\cdot}77)}{(\text{inverse}\log_{10}0{\cdot}77)+1}$$

$$= 85{\cdot}5 \text{ per cent}$$

The posterior probability of linkage is:

(prior probability in favour × conditional probability in favour) ÷ [(prior probability in favour × conditional probability in favour) + (prior probability against × conditional probability against)]

$$= \frac{(0{\cdot}75 \times 0{\cdot}855)}{(0{\cdot}75 \times 0{\cdot}855) + (0{\cdot}25 \times 0{\cdot}145)}$$

$$= 0{\cdot}946$$

$$= 94{\cdot}6 \text{ per cent}$$

Pedigree 2000 contains four surviving women who have not developed breast cancer (although one had ovarian cancer). Two of these women have inherited allele 2 of 42D6 and allele 12 of MFD188, both of which are associated with malignancy elsewhere in the pedigree. The probability that these women have inherited the mutant susceptibility gene *BRCA1* is the product of:

(posterior probability of linkage to susceptibility gene) and (probability of not having a double recombination event between 42D6 and MFD188).

Double recombination between 42D6 and MFD188 might enable mutant *BRCA1* to be inherited from the gene-carrying parent in association with parental alleles from the non-mutant *BRCA1*-carrying chromosome 17. In no Edinburgh family was double recombination noted between any of four polymorphic markers spanning a region of 17q12-21 that was 12–28 cM in length and which included markers 42D6 and MFD188; more than 100 meioses were typed. Thus, an estimated double recombination rate of 1 per cent is probably maximal for the genomic interval between 42D6 and MFD188. The probability that the *BRCA1* mutation has been inherited in these two women is therefore:

$$(0{\cdot}946) \times (0{\cdot}99) = 0{\cdot}937 = 93{\cdot}7 \text{ per cent}$$

The lifetime risk of breast cancer is a summation of absolute risks attached to carrier status probability. These women may be: (1) mutant *BRCA1* carriers; (2) non-carriers in a *BRCA1*-linked family; or (3) either carriers or non-carriers of a different (non-*BRCA1*) susceptibility gene. *Table 4* shows the calculations necessary to arrive at the lifetime risk of breast cancer, which in these women is 84·7 per cent, a value considerably greater than the 46 per cent risk estimated for first-degree relatives of gene carriers from epidemiological studies without the benefit of *BRCA1* linkage data[9].

Two women in pedigree 2000 have inherited neither allele 2 of 42D6 nor allele 12 of MFD188. In this case, the probability that they have inherited the susceptibility gene *BRCA1* is the product of:

(posterior probability of linkage to susceptibility gene) and (probability of having a double recombination event between 42D6 and MFD188)

$$= (0{\cdot}946) \times (0{\cdot}01) = 0{\cdot}009 = 0{\cdot}9 \text{ per cent}$$

Table 4 *Calculation of lifetime risk of breast cancer in three unaffected women who are probable* BRCA1 *carriers as determined by 17q marker data in pedigree 2000*

Carrier status	Probability of status	Lifetime risk of breast cancer attached to status	Product of status and risk
Mutant *BRCA1* carrier*	0·937	0·88	0·824
Carrier of non-mutant *BRCA1* in *BRCA1*-linked pedigree†	0·946 × 0·01	0·09	0·001
Carrier or non-carrier of a non-*BRCA1* gene‡	0·054	0·415	0·022
Total	1·000	—	0·847

*Where lifetime penetrance of *BRCA1* mutation in 61 probable carriers from eight linked pedigrees is 88 per cent. †Where pedigree probability of double recombination event is 1 per cent and lifetime risk of breast cancer in the general population is 9 per cent. ‡Where lifetime risk of breast cancer in female members of non-*BRCA1*-linked pedigrees is estimated[9] to be 41·5 per cent

Table 5 *Calculation of lifetime risk of breast cancer in two unaffected women who are probable non-*BRCA1 *carriers as determined by 17q marker data in pedigree 2000*

Carrier status	Probability of status	Lifetime risk of breast cancer attached to status	Product of status and risk
Mutant *BRCA1* carrier*	0·009	0·88	0·008
Carrier of non-mutant *BRCA1* in *BRCA1*-linked pedigree†	0·946 × 0·99	0·09	0·084
Carrier or non-carrier of a non-*BRCA1* gene‡	0·054	0·415	0·022
Total	1·000	—	0·114

*Where lifetime penetrance of *BRCA1* mutation in 61 probable carriers from eight linked pedigrees is 88 per cent. †Where pedigree probability of double recombination event is 1 per cent and lifetime risk of breast cancer in the general population is 9 per cent. ‡Where lifetime risk of breast cancer in female members of non-*BRCA1*-linked pedigrees is estimated[9] to be 41·5 per cent

The lifetime risk of breast cancer is again a summation of risks according to that relative probability of carrier status; its calculation is shown in *Table 5*. A lifetime risk of 11·4 per cent in these women is little different from that in the general population of 9 per cent[9].

Calculations of lifetime risk in this paper rely on lod scores computed as part of the linkage program Mendel[15], which derives two-point lod scores at 21 discrete recombination distances. Slightly different risk estimates may be obtained from programs that integrate lod scores over a range of recombination distances and in which multipoint analyses have been utilized.

Discussion

A total of 19 women in five pedigrees had a probability of mutant *BRCA1* carrier status that ranged from 84·6 to 98·9 per cent. The lifetime risk of breast cancer ranged from 80·6 to 87·2 per cent. (Three pedigrees contained no surviving women unaffected by breast cancer with *BRCA1* mutation.) A further 37 women in eight pedigrees had odds of mutant *BRCA1* carrier status that ranged from 0·8 to 1·0 per cent. The lifetime risk of breast cancer ranged from 9·8 to 16·4 per cent. Reassessment of risk on the basis of linkage data is therefore capable of identifying women who might benefit from regular breast screening at a younger age than is currently available in many centres. Conversely, women with a strong family history but a low risk of malignancy as determined by 17q marker data analysis can be identified as unlikely to benefit from early breast screening. In pedigree 1 there are seven probable *BRCA1* gene carriers aged 30 years or less who have a lifetime risk of breast cancer of 82·1 per cent. By extrapolation from disease penetrance figures in 61 probable mutant *BRCA1* carriers from all eight linked families, these seven women will have a 2·5 per cent per annum risk of developing breast cancer between the ages of 30 and 50 years. Three or four of them are therefore expected to develop breast malignancy during this age interval. Pedigree 2 contains two women aged 30 years or less who are probably non-mutation carriers on the basis of 17q marker data. Their lifetime risk of breast cancer is 9·8 per cent and between the ages of 30 and 50 years their risk[9] is only 0·05 per cent per annum. These young women might be spared the worry of regular breast screening in this age interval.

An ethical problem lies in the relative insecurity of linkage analysis data. For example, in pedigree 1, the *BRCA1* gene mutation can be identified with almost 85 per cent certainty. Yet there is still a 15 per cent chance that breast cancer in this family arises in consequence of an alternative (non-*BRCA1*) susceptibility gene, in which case the apparent non-mutant *BRCA1* carriers will be at significantly greater risk than that calculated on the basis of probable *BRCA1* linkage. From an ethical standpoint it may therefore be acceptable to await definitive *BRCA1* gene identification to confirm genetic status before informing the patient of personal linkage results. This course of action can be defended if, as is anticipated, definitive identification of *BRCA1* occurs shortly[17]. *BRCA1* identification will enable all women who require risk assessment to undergo genetic analysis without reference to labour-intensive family linkage studies. It is possible, however, that *BRCA1*, like the adenomatous polyposis coli gene, is of considerable size so that extensive sequencing will be necessary to identify mutations within it. At present, a special case may be made for high-risk women in *BRCA1*-linked families who request advice about the merits of prophylactic bilateral mastectomy. In this situation disclosure of personal linkage results, accompanied by counselling on data interpretation, may enable a more informed decision to be made.

An additional one or two genes that predispose to breast cancer have already been identified. These are the p53 tumour suppressor gene, which may contribute 0·5–1 per cent to the total burden of breast cancer[18–20], and possibly the ataxia telangiectasia gene in heterozygotes for the trait[21,22]. Screening of these breast cancer susceptibility genes together with *BRCA1* may enable a small, well defined, high-risk group of women to benefit increasingly from both regular breast screening, and pharmacological and surgical prophylaxis.

Significance of circumferential resection margin involvement after oesophagectomy for cancer

P. M. Sagar, D. Johnston, M. J. McMahon, M. F. Dixon and P. Quirke

Centre for Digestive Diseases, The General Infirmary, Leeds, UK

Correspondence to:
Mr P. M. Sagar, University Department of Surgery, Royal Liverpool University Hospital, Prescot Street, Liverpool L7 8XP, UK

This study examined the influence of tumour involvement of the circumferential resection margin on subsequent local recurrence after oesophagectomy. Fifty patients were studied: 36 men and 14 women of median age 62 (range 44–83) years. Each patient had undergone oesophagectomy at which all macroscopic disease had been removed. Pathological specimens were sectioned tangentially at 0·5–1·0-cm intervals to permit microscopic examination of the circumferential resection margin. Patients were followed and investigated by endoscopy with biopsy and imaging techniques only if symptomatic. Twenty of the 50 specimens demonstrated involvement of the circumferential resection margin. At median follow-up of 36 (range 24–52) months, eleven of these 20 patients had developed histologically proven local recurrence compared with only four of the remaining 30 in whom the resection margin was clear of tumour ($P<0{\cdot}01$)*. Circumferential spread of oesophageal cancer appears to be a significant cause of local tumour recurrence.*

The outlook for patients with oesophageal cancer is poor[1] and overall survival rates at 5 years remain about 5 per cent[2]. Surgical treatment offers the best symptomatic relief[3], but many patients develop local recurrence.

For rectal adenocarcinoma, recurrence is related to failure to remove the tumour completely and involvement of the lateral resection margin is closely associated with subsequent local recurrence[4]. The concept of *en bloc* resection with extensive lymphadenectomy for colorectal cancer is advocated for gastric carcinoma[5,6]. A similar strategy for oesophageal cancer[7] allows low rates of mortality[8], improved survival[9] at 5 years and no local recurrence[10].

This study investigated the significance of tumour involvement of the circumferential resection margin in patients undergoing oesophagectomy for cancer.

Patients and methods

Fifty patients were studied (36 men, 14 women) with a median age of 62 (range 44–83) years. Each patient had undergone oesophagectomy between 1984 and 1989. Preoperative staging included endoscopy, barium contrast study, ultrasonography of the upper abdomen, computed tomography (CT) of the chest and bronchoscopy where indicated. Frozen-section examination of the proximal resection margins was routinely used. None of the patients received adjuvant chemotherapy or radiotherapy. Details of patients were obtained from a retrospective review of case notes and are given in *Table 1*.

The original operative specimen stored in formalin was orientated and pinned under gentle tension to a cork board. The distance from the macroscopic edge of the tumour to the proximal and distal resection margins was measured and the site of the tumour sliced tangentially at 0·5–1·0-cm intervals. Some 2 cm of oesophagus above and below the tumour were included and separate sections taken from the proximal and distal resection margins. All sections were assessed macroscopically (*Figure 1*). Circumferential resection margins were marked with Indian ink to allow histological identification and to prevent false-positive involvement of the margin as a result of poor embedding technique[11].

Measurements were made on each tumour slice of the distance from the tumour edge to the circumferential resection margin and the distance from satellite deposits or lymph nodes involved with tumour to the circumferential margin. The minimum distance between the tumour and the circumferential resection margin was measured by means of a Vernier scale on the microscope stage. Each of the sections was coded and measurements made on two separate occasions; the microscopist was unaware of the clinical outcome. Specimens were positive if tumour extended to within 1 mm of the circumferential resection margin.

Table 1 *Details of patients*

	Circumferential resection margin involvement		
	Positive ($n=20$)	Negative ($n=30$)	Total ($n=50$)
Median (range) age (years)	64 (48–83)	59 (44–77)	62 (44–83)

Values in parentheses are percentages

Patients were followed and investigated by endoscopy with biopsy and imaging techniques if they became symptomatic.

Statistical analysis

Non-parametric data were compared using the Mann–Whitney U and χ^2 tests. Survival was assessed from operation because the time between diagnosis and surgery was short (less than 4 weeks) in each patient. Life-tables were drawn by the Kaplan–Meier method and differences in survival between patients with and without involvement of the circumferential resection margin calculated by the log rank test[12].

Results

The median distance from the oesophageal tumour to the circumferential resection margin in patients with a margin of

0007-1323/93/111386-03 © 1993 Butterworth–Heinemann Ltd

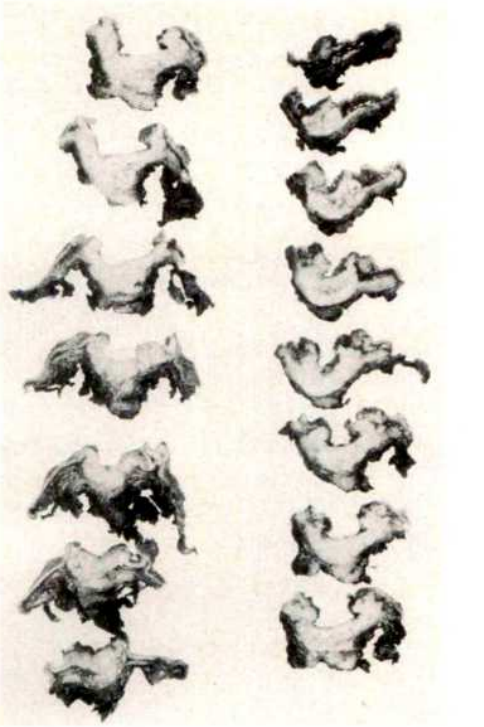

Figure 1 *Tangential slices of oesophagus laid out for inspection and sampling of the circumferential resection margin*

normal tissue included in the resection was 10·0 (interquartile range 6·0–15·5) mm (correlation coefficient R_S between two separate measurements of distance 0·93). The lesion extended to the circumferential resection margin in 20 of the 50 patients, 11 of whom had local tumour recurrence. Of the remaining 30 patients without involvement of the circumferential resection margin, only four had local tumour recurrence ($\chi^2 = 8{\cdot}04$, 1 d.f., $P < 0{\cdot}01$). Of the 15 patients in whom local recurrence occurred, the diagnosis was made by endoscopy with positive biopsy in 11 and by CT of the mediastinum in four. The median length of follow-up was 36 (range 24–52) months.

There was no difference in age, sex distribution, risk factors, preoperative parameters, operative technique, or site, length or histological type of tumour between patients with and without circumferential resection margin involvement.

The median time from operation to diagnosis of local recurrence in the 11 patients with involvement of the circumferential resection margin was 12 (range 4–22) months and the median survival time 15·5 (range 8–24) months. The median time to local recurrence in the four patients without circumferential resection margin involvement was 9 (range 8–13) months and the median survival time of these patients 17·5 (range 9–23) months. The median survival time of the nine patients with involvement of the circumferential resection margin but in whom there was no evidence of local recurrence was 21 (range 13–36) months.

The proximal resection margin was not involved with tumour in any specimen and the median distance of this margin from the tumour in the fixed specimen was 5·0 (range 1·5–8·0) cm. The distal resection margin was also free from tumour in each specimen (median distance 7·8 (range 3·0–30·0) cm). Vascular invasion was present in seven patients and neural invasion in one.

The number of lymph nodes with metastatic involvement shared some correlation with the presence of involvement of the circumferential resection margin ($R_S = 0{\cdot}45$, $P = 0{\cdot}02$).

Four patients had no involvement of the circumferential resection margin but subsequently developed local recurrence of tumour: three had undergone transhiatal blunt oesophagectomy by the Orringer method and, in the fourth, marked vascular invasion by tumour was found.

Of the 20 patients with involvement of the circumferential resection margin, only five survived for 2 years, whereas 14 of the 30 patients who did not have involvement of the circumferential resection margin survived for 2 years (log rank $\chi^2 = 4{\cdot}33$, 1 d.f., $P < 0{\cdot}05$).

Discussion

The idea that depth of penetration of the oesophageal wall by tumour is an independent predictor of prognosis was first suggested[13] in 1982. A staging system based exclusively on wall penetration, lymph node involvement and systemic metastasis has been used to select patients for either *en bloc* or standard oesophageal resection[14].

The present study is open to a number of criticisms. It was non-consecutive and retrospective. Patients were excluded if they failed to survive the operation or were inadequately followed up. There was a predominance of patients with adenocarcinoma of the lower third of the oesophagus. The entire resection specimen was required to allow thorough assessment of the circumferential resection margin. These exclusions may be a potential source of bias.

Although the specimens had been examined previously, they were largely intact and relatively little tissue had been removed for histological examination. The original slides were reviewed to confirm the status of the resection margins. There were adequate amounts of healthy tissue around the tumour in the resected specimens (median clearance 10·0 mm) but this may have been an overestimate as measurements were taken to the furthest point at which healthy tissue was evident. The critical factor, however, appeared to be the presence or absence of tumour at the margin rather than the absolute distance between the tumour and margin.

Recurrence was identified only in patients who became symptomatic and this too may be an underestimate. Although recurrent disease was diagnosed with endoscopy in 11 patients, this probably does not represent implantation or resection-line recurrence; all resection lines were clear at frozen-section and subsequent paraffin-section examinations. CT was performed in seven of the 11 patients and demonstrated extensive mediastinal disease that extended distally and was in continuity with tumour at the level of the anastomosis.

Blunt transhiatal resection of the oesophagus without thoracotomy has been advocated[15], with acceptable morbidity[16]. This technique remains controversial[17] and some argue that it does not permit adequate resection for cancer[7–9,18]. In the present study, three of the four patients in whom local recurrence developed despite clear resection margins had undergone transhiatal oesophagectomy. This small number of patients does not allow statistical analysis.

En bloc resection of the oesophagus with radical lymphadenectomy is associated with favourable survival rates[7,19]. Such resections are more likely to allow complete removal of the tumour. It is possible that *en bloc* resection reduces the likelihood of involvement of the circumferential resection margin and this may partly explain the improved survival[17].

This retrospective study suggests that microscopic involvement of the circumferential resection margin is related to subsequent local recurrence and decreased survival. A prospective study will analyse this hypothesis.

Announcement

European Surgical Fellowships

The Council of *The British Journal of Surgery* is pleased to announce the availability of European Surgical Fellowships for 1994. Last year four Fellowships were awarded, to Dr Jose Luis Aguayo-Albasini (Spain), Mr R. M. Charnley (Nottingham), Mr S. D. Heys (Aberdeen) and Mr T. G. John (Edinburgh).

It is Council's intention to offer European Surgical Fellowships again in 1994. Each Fellowship will have a value of up to £3000 and is intended to allow surgeons working in the UK to visit centres in other European countries or surgeons working in other European countries to visit the UK. Applicants must be under 40 years of age and should submit details of their proposed itinerary and its anticipated cost, together with a copy of their *curriculum vitae* and two letters of support from senior colleagues. They should explain briefly how such a visit might broaden their experience and assist their career. Fellowships will not be awarded solely for the purpose of attending courses or meetings.

Applications should be sent to the Company Secretary, Professor D. C. Carter, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, by 1 February 1994.

The value of CD4 and CD8 monoclonal antibody therapy in tolerance induction has been demonstrated in rodent transplant models. In this paper the immunosuppressive potential of CD4 and CD8 monoclonal antibodies for dog renal allografts was evaluated as a preliminary to tolerogenic studies in this large animal model. Monoclonal antibodies were given for a maximum of 10 days after transplantation. Therapy was stopped prematurely following adverse reactions associated with the recipient developing an antibody response against the foreign (rat) therapeutic monoclonal antibody. Blood trough levels of CD4 and CD8 antibodies indicated that saturating doses were achieved. Although neither CD4 nor CD8 alone prolonged allograft survival (rejection by day 7), combination of CD4 and CD8 antibodies resulted in good graft function for a median of 14 days. The effect of removing circulating T lymphocytes was also assessed using a lytic Thy-1 monoclonal antibody. Alone Thy-1 had little effect but, when combined with CD4, the median allograft survival time was increased to 15·5 days. Reduction of the number of circulating T lymphocytes appears complementary to blockade of CD4 for immunosuppression, while blockade of CD4 combined with removal of CD8 also favours allograft survival.

In rodent models a short course of therapy with monoclonal antibodies to the CD4$^+$ and CD8$^+$ T lymphocyte subsets has been shown to induce tolerance to skin and vascularized grafts across fully allogeneic strain combinations[1–3]. However, tolerance induction in rodents is relatively easy to achieve, as illustrated by the observations that a 2-week course of cyclosporin induces tolerance in PVG rats to DA cardiac allografts[4] whereas a fully immunosuppressive dose of cyclosporin can be given for 100 days to dogs in receipt of renal allografts without altering the tempo of rejection on withdrawal of the drug[5]. Promising tolerogenic therapies thus need to be developed in a large animal model before being considered for clinical application.

The preclinical evaluation of monoclonal antibody therapies may be performed in two ways. One is to use a primate model, selecting monoclonal antibodies raised against human leucocytes that cross-react with the primate leucocytes. Alternatively, species-specific monoclonal antibodies may be generated for a selected large animal model such as pig or dog. Following the latter approach, a panel of rat antidog monoclonal antibodies has been developed. This paper describes the efficacy of CD4 and CD8 monoclonals in prolonging renal allograft survival in mismatched mongrel dogs.

Materials and methods

Monoclonal antibodies

Hybridomas were produced by fusion of rat Y3/Ag1.2.3 myeloma cells with spleen cells from rats immunized with canine leucocytes, thymocytes or concanavalin A-activated lymphoblasts. The resulting monoclonal antibodies were characterized by immunofluorescence, immunoprecipitation, immunohistology and according to their properties in mixed lymphocyte reaction (MLR) and cell-mediated lympholysis assays. Selected hybridomas were grown and injected into pristane-primed (DA × LOU) F_1 rats for the production of ascites. Antibody was obtained by precipitation of the ascites with 50 per cent saturated ammonium sulphate, followed by dialysis into phosphate-buffered saline. Before administration the antibodies were passed through a 2-μm filter. *Table 1* shows the antibodies used, their isotypes and characteristics.

Dogs

Mongrel dogs of either sex weighing between 12 and 24 kg were obtained from this department's breeding colony. Donor–recipient pairs were selected on the basis of MLR-typing data, each pair being a double MLR-defined haplotype mismatch, with a stimulation index of over 25 units in a 6-day MLR. Each dog underwent bilateral nephrectomy and received a single allograft from its pair, transplanted heterotopically into the right iliac fossa with end-to-side vascular anastomoses (6/0 polypropylene) and a ureteroneocystostomy (6/0 polydioxanone).

Table 1 *Monoclonal antibodies used*

Specificity	Antibody	Hybridoma clone	Isotype	*In vivo* effects	Antigen distribution
CD4	YK9-302	YKIX 302.9.3.7	IgG_{2a}	Immunomodulation; partially depleting	T helper cell subset; also on neutrophils in the dog
CD8	YC8-55	YCATE 55.9.1	IgG_1	Depletion and immunomodulation	Cytotoxic T cell subset
	YC8-60	YCATE 60.3.9	IgG_1		
Thy-1	YK9-337	YKIX 337.217.7	IgG_{2b}	Depletion	Peripheral T cells, thymocytes, vascular endothelium especially in renal medulla

Monitoring

Blood was taken daily for the measurement of both circulating monoclonal antibody levels and host antibody responses to the monoclonal antibody (the antiglobulin response). The assays have been described previously[2-6]. Lymphocyte subsets were determined twice weekly and serum biochemistry three times a week. The survival endpoint was taken as the day the serum creatinine level rose above 300 μmol/l.

Therapy

The antibodies were administered daily by slow intravenous injection. The therapeutic groups are given in *Table 2*. In each group therapy

Table 2 *Results of antibody therapy*

Group	No. of dogs	Antibody specificity	Daily dose*	Time to rejection (days)†	Time to clinical reaction (days)‡	Time to antiglobulin response (days)§
1	2	CD4	20 mg	5, 7	None	None, 6
2	2	CD8	2·5 mg	5, 7	6, 7	4, 4
3	2	Thy-1	5 mg	9, 9	6, 6	6, 6
4	2	Thy-1	5 mg × 2 days	7, 9	None	6, 6
5	4	CD4 CD8	10 mg 5 mg	10, 13, 15, 18	None	CD4: none, none, 5, 13 CD8: 4, 11, 13, 13
6	4	CD4 Thy-1	10 mg 5 mg × 2 days	12, 15, 16, 17	None, none, 7, 8	CD4: 9, 9, 9, 14 Thy-1: 7, 7, 7, 8

*Daily dose of antibody starting 2 days before transplantation and continued to day 10, death or the occurrence of an adverse reaction, with the exception of group 4 which received antibody on the 2 pretransplant days only. †Day after transplantation on which the serum creatinine was ⩾300 μmol/l. On no treatment allograft rejection occurs by day 7. ‡Day after transplantation of an adverse reaction necessitating cessation of antibody therapy. §Earliest day after transplantation on which an antiglobulin response was detected

was started 2 days before transplantation. The limited amount of antibody available restricted the duration of therapy and numbers of dogs in each group. The first treatment groups involved antibodies of a single specificity. This was followed by groups receiving either combined treatment with CD4 and CD8 antibodies, or CD4 and Thy-1 antibodies. Therapy was discontinued prematurely on occurrence of an adverse reaction immediately following antibody administration. These reactions, characterized by ataxia, micturition, defecation and loss of consciousness, resolved spontaneously after 10–15 min. Similar anaphylactoid reactions have been reported in dogs receiving polyclonal equine anticanine leucocyte serum[7].

Results

Retrospective control studies have shown that untreated MLR-mismatched mongrels reject renal allografts (creatinine level ⩾300 μmol/l) by day 7, most doing so by day 6.

CD4 therapy (group 1)

A CD4 antibody dose of 20 mg/day failed to prolong graft survival and both dogs rejected the allograft by day 7. Circulating CD4 monoclonal antibody was detectable in the serum throughout at around 10 μg/ml. An antiglobulin response developed in one of the two dogs but neither suffered an adverse reaction (*Table 2*). *Figure 1a* shows the peripheral lymphocyte changes during therapy with a decrease in circulating T cell numbers following transplantation. $CD4^+$ cells were reduced in number and coated with the CD4 antibody throughout.

CD8 therapy (group 2)

Two dogs received a combination of 2·5 mg/day of two different CD8 antibodies (YC8-55 and YC8-60). Again there was no therapeutic benefit and both animals rejected the allograft by day 7. Circulating CD8 monoclonal antibodies were present up to day 4, when both dogs developed an antiglobulin response. An adverse reaction to the antibody occurred on days 6 and 7 respectively. The antibody combination produced over 90 per cent depletion of $CD8^+$ cells from the peripheral blood.

Thy-1 therapy (groups 3 and 4)

When given Thy-1 monoclonal antibody 5 mg/day the recipients exhibited a slight prolongation in allograft survival to day 9. Both dogs had adverse reactions to the antibody requiring cessation of therapy on day 6. The Thy-1 antibody depleted over 90 per cent of circulating T cells, with numbers slowly returning by day 7. A similar depletion of T cells was achieved if only two daily doses were given (group 4; *Figure 1b*). All four dogs developed an antiglobulin response by day 6. Circulating monoclonal antibody was detected only transiently (up to 1 h) after injection.

Combined CD4–CD8 therapy (group 5)

In this group the CD4 antibody dose was reduced to 10 mg/day, which maintained trough levels above 1 μg/ml. The CD4 antibody was combined with a total dose of CD8 5 mg/day, made up of either YC8-55 alone or YC8-55 plus YC8-60 (2·5 mg/day each). Survival time ranged from 10 to 18 (median 14) days. No difference was observed if YC8-60 was included. None of the dogs in this group had an adverse reaction to therapy. All four dogs made an antiglobulin response to the CD8 antibodies, but only two of the four made responses to the CD4 antibody. *Figure 1c* shows the changes in peripheral lymphocytes on combined therapy.

Combined CD4–Thy-1 therapy (group 6)

A combination of CD4 and Thy-1 antibodies was given to four dogs, the Thy-1 being given for 2 days before transplantation to deplete the circulating lymphocyte mass before engraftment, and the CD4 antibody being continued to day 10 (*Figure 1d*). In this group the survival time was extended to a median of 15·5 days. Two dogs had adverse reactions necessitating premature cessation of therapy (days 7 and 8). Antiglobulin responses to both Thy-1 and CD4 antibodies were detected in all four dogs.

Discussion

Donor-specific tolerance to an organ allograft remains a goal of clinical organ transplantation. In rodents such a state can be induced using combinations of CD4 and CD8 antibodies. The antibody requirement varies according to the degree of immunological challenge posed by the donor organ. Non-depleting CD4 therapy alone is sufficient to induce tolerance to major histocompatibility complex (MHC) mismatched cardiac allografts in some mouse models[3,8]. Tolerance to skin allografts is more difficult to induce than that to vascularized grafts. Across multiple minor antigen mismatches, skin graft tolerance can be induced using a combination of non-depleting CD4 and CD8 antibodies, but combinations of depleting and non-depleting CD4 and CD8 antibodies are required where a full MHC mismatch is involved (CBA/Ca recipients of BALB/c skin, $H\text{-}2^k$ into $H\text{-}2^d$)[2].

The ability to induce tolerance is related to the degree of mismatch between donor and recipient, and to the capacity of the recipient's immune system. Even in rodents the amount of surplus capacity behind an immune response is large, such that only a fraction of the normal T cell population is required to reject an allograft[9,10]. Large animals have a large immune system, with a correspondingly large surplus capacity. Thus the induction of tolerance in large animal models and humans is more difficult than in rodents.

The dog has been shown to be a good preclinical model for the evaluation of immunosuppressive therapies: both azathioprine and cyclosporin were assessed in dog renal allograft experiments before being extended into clinical practice[11,12]. In the present study outbred mongrels were selected as a model to assess the efficacy of CD4 and CD8 monoclonal antibodies in prolonging allograft survival. Double-haplotype mismatched donor–recipient pairs gave a high degree of immunological challenge that, if untreated, always resulted in rejection by day 7.

It was found that targeting either inductor or effector arms of the immune response individually with CD4 or CD8 antibodies alone did not alter the tempo of renal allograft rejection, in spite of evidence that adequate monoclonal antibody levels were achieved to ensure coating of the target T cell populations. T cell depletion with the depleting Thy-1 antibody alone also made little difference to allograft survival, in spite of achieving a reduction of over 90 per cent in circulating T cell numbers.

When both inductor and effector arms were targeted together with combined CD4–CD8 antibody therapy, survival was extended to a median of 14 days. This extended survival could be interpreted as the combined therapy being immunosuppressive for the duration of treatment, followed by rapid rejection once therapy ceased. When the excess capacity of the immune system was first reduced by Thy-1 treatment, survival could be prolonged to a median of 15·5 days by CD4 antibodies in the absence of additional CD8. Although this suggests that the efficacy of CD4 is improved by reducing the overall number of circulating T cells, in fact both $CD4^+$ and $CD8^+$ cell numbers are depleted and the effect of Thy-1 may in part be similar to that of CD8 therapy.

The duration of effective monoclonal antibody treatment is restricted by the occurrence of antiglobulin responses directed to the idiotypic and isotypic parts of the monoclonal antibody, preventing binding and hastening clearance from the serum. This has not been such a problem in rodent studies, where CD4 antibodies have been shown to induce tolerance to both themselves and to coadministered antibodies[13]. Similarly, the incidence of antiglobulin responses was less in dogs on CD4 therapy. In the present experiments only one of the two dogs on CD4 alone and two of the four receiving combined CD4–CD8 therapy developed an antiglobulin response. When CD4 therapy was given in conjunction with either Thy-1 or

CD8 the onset of the antiglobulin response to these antibodies was frequently delayed.

The aetiology of the anaphylactoid reaction following administration of antibody occurring between days 6 and 10 is uncertain. It is probably related to the antiglobulin response, especially if this response is mediated by immunoglobulin (Ig) E.

Although allograft survival was prolonged in these studies, a more extensive prolongation will be sought during the development of tolerogenic therapies. One approach would be to increase the dose of monoclonal antibody since 20 mg CD4 (group 1) represents a dose of around 1 mg/kg, contrasting with doses of 4 g/kg used in some rodent studies[2]. The present results indicate that 1 mg/kg CD4 alone was ineffective in this highly mismatched model (stimulation index over 25 units), whereas the same protocol using OKT4A 0·3 mg/kg (a mouse IgG_{2a} antihuman CD4 antibody) in cynomolgus monkeys prolonged allograft survival to a median of 23 days, compared with rejection by day 11 in untreated controls[14]. This beneficial effect using low-dose CD4 alone in cynomolgus monkeys is most likely to relate to the degree of mismatch, since the MLR stimulation indices ranged from 2 to 20 without exclusion of possible shared haplotypes[15], and a wide range of rejection times was noted (8–49 days), although species differences *per se* may be involved. A single high dose (10 mg/kg) of OKT4A on day 0 also resulted in prolonged renal allograft survival (median 36 days) in cynomolgus monkeys, further illustrating the therapeutic efficacy of CD4. The present results indicate that the immunosuppressive effect of CD4 is complemented by combination with other monoclonal antibodies that either deplete or block the immune response.

Other primate experiments have described a beneficial effect when CD4 antibodies were combined with conventional immunosuppression. Jonker *et al.*[16] used a pair of depleting and non-depleting CD4 antibodies (~1 mg/kg each of OKT4 and OKT4A) for 21 days starting at day −2, together with continuous prednisolone and azathioprine compared with prednisolone and azathioprine alone. With CD4 a median of 37 days survival contrasted with a median of 12 days for prednisolone and azathioprine alone.

In conclusion, the present results support the observations in rodent experiments that, as the magnitude of the immunological challenge posed by an allograft rises, increasingly more potent therapeutic monoclonal antibody therapies are required to induce tolerance. The hierarchy of such therapies increases from CD4 therapy alone, through a combination of non-depleting CD4 and CD8 therapies, to a combination involving depleting antibodies. In mismatched mongrel dogs CD4 therapy (1 mg/kg) alone is insufficient to prolong renal allograft survival. Prior depletion of the recipient's lymphocyte mass or combination therapy with CD4 and CD8 antibodies is required. For the induction of tolerance in the dog it is possible that a more prolonged period of therapy involving depleting and non-depleting CD4 and CD8 antibodies and/or additional immunosuppressive drug therapy will be required.

Patient selection and timing of dynamic computed tomography in acute pancreatitis

Dynamic computed tomography (CT) is the most accurate method for determining the extent of necrosis in acute pancreatitis. Debate exists, however, regarding patient selection and the optimal timing of CT. This study examined selection based on biochemical and/or clinical criteria and the influence of delayed dynamic CT performed 5–10 days after the onset of an attack. A total of 120 patients with acute pancreatitis were studied. Dynamic CT was performed if any of the following criteria were identified: a biochemically severe attack (according to Glasgow criteria) in the first 24 h, C-reactive protein (CRP) level above 120 mg/l in the first 3 days or failure of clinical resolution within 7 days. Of 42 patients selected for CT, five died from multisystem organ failure before day 5. There were no deaths or delayed complications in the 78 patients not selected for scanning. Positive Glasgow criteria alone in the scanned group had a sensitivity for predicting necrosis (as recognized by CT) of 22 per cent and a specificity of 20 per cent. Measurement of CRP level alone had a sensitivity of 26 per cent and specificity of 80 per cent. Failure of clinical resolution had a sensitivity of only 7 per cent but a specificity of 100 per cent. The combination of Glasgow criteria and CRP level had a sensitivity of 44 per cent and specificity of 100 per cent. Delayed complications (pseudocyst, five; infection, six) occurred only in patients with necrosis, and there were two deaths. An 'at-risk' group can be identified for CT on the basis of biochemical and clinical observations. Neither routine nor emergency dynamic CT in acute pancreatitis seems justified.

The principal benefit of early assessment of severity in acute pancreatitis is the selection of patients who require intensive monitoring and therapy. Early identification of an at-risk group of patients who also have gallstone aetiology allows early endoscopic sphincterotomy with a consequent reduction in mortality rate[1]. Almost all the mortality and morbidity of acute pancreatitis is concentrated in the 25 per cent of patients classified as having severe disease. Those predicted to suffer a mild attack have a very low mortality rate of 1–2 per cent[2–4]. Clinical assessment tends to be subjective and is of limited value in the early detection of severe acute pancreatitis[5]. Single[6–8] and multiple[9] biochemical criteria and peritoneal fluid analysis[10] have all been used as prognostic indicators. Abdominal computed tomography (CT), although highly sensitive for the diagnosis of pancreatitis[11], has not been shown to improve on modified Glasgow criteria (*Table 1*) in predicting the severity of an attack[12,13]. CT is, however, the most accurate method for determining the presence and extent of pancreatic necrosis[14] and is undoubtedly useful in identifying local pancreatic complications[15].

Debate remains regarding patient selection and the optimal timing of CT in acute pancreatitis. The purpose of this prospective study was to identify criteria by which to select patients for CT and to determine whether delaying the scan until the end of the first week has any influence on outcome.

Patients and methods

This study investigated 120 consecutive patients admitted with a diagnosis of acute pancreatitis. The median age was 52 (range 22–87) years in 61 men and 58 (range 21–93) years in 59 women. The aetiology is shown in *Table 2*. Patients were selected for CT by satisfying at least one of three criteria: three or more positive modified Glasgow criteria within the first 24 h, C-reactive protein (CRP) level above 120 mg/l within the first 3 days and failure of clinical resolution within 7 days. The CRP level was based on the work of Mayer *et al.*[6] and Buchler and colleagues[16] implying a 95 per cent chance of necrosis being present above this value. Failure of clinical resolution at 7 days included all patients with persistent clinical features consistent with acute pancreatitis or its complications. In all, 42 patients satisfied these criteria, of whom 37 underwent dynamic contrast-enhanced CT between 5 and 10 days after admission. Patients thought to have a biliary aetiology also

underwent endoscopic retrograde cholangiopancreatography (ERCP) and, where appropriate, sphincterotomy within the first 48 h of admission. Necrosis was identified on CT by a consultant radiologist; both intrapancreatic and extrapancreatic necrosis were included. CT was performed on a Siemens DRH scanner (Siemens, Sunbury-on-Thames, UK). Patients were given 20 ml Conray 280 (May and Baker, Dagenham, UK) in 1 litre orange juice beginning 90 min before scanning. Non-enhanced CT was initially performed (8-mm cuts), followed by rapid-sequence scans beginning with a 50-ml bolus of Niopam 300 (Merck Pharmaceuticals, Alton, UK) with injection of a further 50 ml over the next 30 s. Slices of 4 mm were taken with a scan time of 4 s per scan. Fine-needle aspiration of necrotic areas was performed under CT control in all patients with persisting clinical abnormalities at the time of scanning.

Results

All 78 patients classified as having a mild attack of pancreatitis on the three predictive criteria recovered without morbidity or mortality. Of the 42 patients classified as having a severe attack, five died within 72 h of admission. Four of these five were over the age of 80 years and died from multisystem organ failure. One patient died 1 h after ERCP with sphincterotomy and stone extraction, from an acute cardiac event characterized by sustained electrical activity in the absence of cardiac output.

Necrosis was identified by CT in 27 of the 37 surviving patients with severe disease. There were no cases where necrosis could be confidently identified as exclusively extrapancreatic. The ten patients without necrosis recovered without complication. The criteria for CT and subsequent correlation with the presence of necrosis are shown in *Table 3* along with sensitivities, specificities and predictive values. Eleven patients in whom necrosis was identified ultimately came to surgery. Five of these had symptomatic pseudocysts that did not resolve spontaneously or after a single attempt at percutaneous aspiration. Cyst–enteric anastomosis was performed 27–62 days after onset of the attack and all five patients recovered uneventfully. Six patients were found to have infected necrosis with mixed intestinal flora on fine-needle aspiration; all underwent operation designed to remove all necrotic pancreatic and peripancreatic tissue 11–23 days after onset of the attack. (Two patients required a second CT scan with guided aspiration to confirm infection.) There were two deaths after surgery for infected necrosis. The overall mortality rate for the entire series of 120 patients was 6 per cent. In the group with disease predicted to be severe the mortality rate was 17 per cent (18 per cent in patients undergoing surgery).

Discussion

The age–sex distribution of patients with pancreatitis, mortality rate (6 per cent), incidence of clinically apparent pseudocyst (4 per cent) and of infected necrosis (5 per cent) in this study are similar to those of others carried out in the UK[13].

Patients who die from acute pancreatitis tend to do so either early, usually in the first week, from organ failure (adult respiratory distress syndrome, acute renal failure, myocardial insufficiency) or late, from sepsis when necrotic pancreatic and peripancreatic tissues become secondarily infected[17–22]. That early surgery on the pancreas might reduce mortality in the early phase has never been demonstrated[23–27]; there thus seems little justification for recommending emergency CT as a way of defining an acute surgical group that does not exist. It also seems illogical to propose the widespread use of CT as a means of identifying a 'severe' group of patients, since direct assessments of physiological disturbance can be made from the organ systems concerned that are known to identify reliably patients requiring intensive support[3,5–8]. Published opinion regarding the value of CT in this context seems divided[28–33].

On the other hand, the reliability of early biochemical prognostic indicators in identifying patients who will go on to develop late sepsis is open to question. The implication that an acute-phase response protein (CRP) might be highly sensitive in this context merited evaluation. For these reasons, CT was deferred for 5–10 days by which time five patients, whose management we contend would not have been influenced by the result of CT, had died. Since the removal of necrotic pancreatic tissue in the first week of an attack does not improve survival, there seems no reason to use CT to demonstrate necrosis at the time of admission.

Among the 78 patients not selected for CT there were no deaths or late complications. If any of these patients had necrosis, it was only a radiological feature of no clinical relevance. Of the 37 patients who underwent CT, a combination of biochemical tests and clinical assessment identified all those at risk of developing late local sepsis. The inadvisability of relying on Glasgow criteria to predict necrosis in the at-risk group was evident since necrosis was not identified by CT in eight of 26 such patients. Although CRP level is a more useful predictor of necrosis (false-positive results were obtained for only two of 21 patients), the problem with both tests is that, considered individually, they miss an unacceptably high proportion of patients in whom necrosis is recognized by CT. The value of these tests, however, is that, if either or both are positive, there is little chance of missing an at-risk patient, at the expense of a false-positive rate of 29 per cent. If CT is then additionally offered only to patients without biochemical criteria but who remain unwell at the end of the first week of illness, all at-risk individuals may be identified. The performance of ten unnecessary CT scans in 37 patients seems acceptable, bearing in mind that 11 of the 37 ultimately required surgery.

It is apparent that not all patients require a costly CT scan for prognostic purposes and, since the benign nature of the majority of cases can be predicted by biochemical and clinical criteria, CT should be limited to a selected group of patients. Further reductions in the mortality rate attributable to late sepsis might be achieved by refining the selection process for CT further, particularly for patients requiring repeat scans to optimize the nature and timing of subsequent intervention. Routine or emergency CT in all patients with acute pancreatitis cannot be justified.

A prospective comparison of laparoscopically assisted (n = 11) and conventional (n = 14) anterior resection in patients with sigmoid colon or upper rectal cancer was carried out. Patients were not randomized: age and the presence of metastases determined the type of surgery. Laparoscopic assistance was used to mobilize the tumour and minimize the abdominal incision. This was achieved in all patients and six of the 11 required only a muscle-splitting incision. The mean(s.d.) operating time was longer for laparoscopic than conventional surgery (205(31) versus *123(26) min, P = 0·01). The mean(s.d.) time to reintroduction of normal diet (2·5(0·2)* versus *3·6(0·3) days, P = 0·01), postoperative analgesia requirement (2·6(0·4)* versus *7·4(2·1) doses of pethidine, P = 0·01) and length of hospital stay (12·3(3)* versus *14·3(6) days, P = 0·08) were less in the laparoscopic group. Histopathological examination of the resection specimens showed similar results for the two procedures. Major complications were few and occurred in a similar proportion of patients treated laparoscopically or conventionally. Laparoscopically assisted anterior resection is technically feasible, adequate tumour excision can be achieved and recovery after operation is enhanced.*

Laparoscopic surgery can reduce the trauma of access and improve recovery after operation, notably in cholecystectomy[1,2]. Similar benefit may derive from laparoscopic bowel surgery[3–5] but the technical problems are greater, including tissue handling, anastomosis and removal of resected material from the abdomen. An abdominal incision is usually required for specimen removal but it can be reduced in size (laparoscopically assisted surgery).

Adequate tissue resection is of utmost importance in colorectal malignancy and must not be compromised by minimally invasive surgery. Some centres have restricted laparoscopic approaches to patients with benign disease and/or requiring limited procedures[3,6], whereas others have concentrated on right-sided lesions[7]. Colorectal cancer is the most common indication for large bowel surgery and 60 per cent of such tumours occur in the rectum and sigmoid colon. Laparoscopic excision of the distal large bowel is likely therefore to have the greatest impact.

This study compares laparoscopically assisted sigmoid colectomy and anterior resection of the rectum with conventional surgery.

Patients and methods

Patients presenting with carcinoma of the sigmoid colon or proximal rectum were studied. Patients were excluded if they had a distal rectal tumour (requiring anastomosis within 5 cm of the dentate line or abdominoperineal resection), a fixed mass palpable rectally or abdominally, or if they had received previous radiotherapy or extensive abdominal surgery. Those aged over 65 years and/or with metastatic disease not treatable by surgery were selected for a laparoscopic procedure. Operation was performed subject to patient agreement and availability of sufficient operating time. Younger patients, including those with three or fewer liver metastases confined to one lobe, were treated by conventional surgery. Patients were not randomized to either type of operation.

Bowel preparation was administered 24 h before surgery and prophylactic broad-spectrum antibiotics prescribed. A urinary catheter and nasogastric tube were used in all patients and surgical drains placed in the pelvis at the end of the procedure. Operating time was measured from the first incision to reversal of anaesthesia.

Laparoscopically assisted surgery

Laparoscopic operations were performed by a team of four surgeons (including the camera operator) with the patient placed head-down in the Lloyd-Davies position. Laparoscopy was performed via a subumbilical incision with four accessory cannulas. Operative steps included: (1) mobilization of the sigmoid colon up to the splenic flexure; (2) division of the inferior mesenteric artery; (3) division of the mesentery including the marginal artery; (4) mobilization of the rectum; (5) division of the bowel distal and proximal to the tumour; and (6) anastomosis. The extent of laparoscopic surgery was determined during the procedure; in this pilot study an incision determined by the position of the tumour was made before step 6. This was usually a suprapubic incision for rectal tumours and in the left iliac fossa for sigmoid lesions.

Conventional surgery

Operations were performed with the patient supine or in the Lloyd-Davies position through a midline abdominal incision.

For both types of surgery complete local tumour excision was carried out and the inferior mesenteric artery ligated as far proximal as possible to maximize lymph node clearance. Specimens were submitted for histological examination; the pathologist was unaware of the method of operation.

After operation patients were prescribed pethidine approximately 1 mg kg^{-1} every 3 h as required or dihydrocodeine tablets 30 mg every 4 h as required. For nausea, metoclopramide 10 mg every 8 h was given orally or by intramuscular injection. Early mobilization was encouraged. The nasogastric tube was withdrawn when drainage was less than 100 ml in 12 h. A fluid diet was started when bowel sounds returned and, if well tolerated, solid food was given thereafter. Pain and nausea were assessed 24 h after surgery using a visual analogue scale (10-cm horizontal line without graduations).

Patients who required only basic nursing and were not sufficiently self-caring to be discharged home were transferred to a convalescent ward. All patients were seen in an outpatient clinic 4–8 weeks after discharge.

Statistical analysis

Results of laparoscopically assisted and conventional surgery were compared using the Mann–Whitney *U* test for variables requiring a

comparison of central tendency only. For measurements of postoperative recovery with a time trend the Mantel–Cox test was employed.

Results

Eleven patients underwent laparoscopically assisted resection and 14 conventional open surgery. Clinical data are summarized in *Table 1.*

The tumour was fully mobilized in all patients and the blood supply divided in eight of 11 during laparoscopic surgery. A grid-iron incision in the left lower quadrant was used in six patients and a Pfannenstiel incision in five. In one patient sutured anastomosis was performed on the surface and ten underwent stapled intra-abdominal anastomosis (cross-stapling technique with circular stapled anastomosis through the transverse staple line) performed under direct vision through the abdominal incision. One patient had an air leak on testing of the anastomosis, which was rectified by sutures after modest extension of the wound.

At conventional surgery six patients had sutured and eight stapled anastomosis. All anastomoses were air-tight on testing. The mean(s.d.) operating time was significantly longer for laparoscopic surgery (205(31) *versus* 123(26) min, *P*=0·01).

The time to reintroduction of normal diet, postoperative analgesia requirement and length of hospital stay were all reduced in patients undergoing laparoscopic operation (*Table 2*). There was no difference between the two groups in the time to removal of the nasogastric tube or the time at which patients first reported passing flatus. Diet was tolerated earlier by patients treated laparoscopically and intravenous fluids were required for longer after open surgery. At 24 h after operation, pethidine dosage and visual analogue scale scores for pain and nausea showed no differences between the two groups. Subsequent requirement for narcotic analgesia was significantly reduced in patients undergoing laparoscopic resection.

B	4	9
C	5	4
Carcinoid	1	0
No. of nodes resected*	10 (2–14)	13 (2–18)
Length of bowel resected (cm)*	14 (11–21)	15 (7–25)
Distal resection margin (cm)*†	2·0 (0·5–5)	2·5 (2–5)

*Values are median (range). †Does not include 'doughnut' resected by staple gun. There were no significant differences between the two groups

Complications occurred in similar proportions of each group (*Table 3*). One patient undergoing laparoscopic resection with adhesions from previous surgery developed signs of peritonitis on the fifth day and laparotomy was performed. A perforation in the small bowel was found and repaired; the patient made a full recovery but hospital stay was prolonged to 29 days. After conventional surgery, one patient developed left loin pain at 7 days and unilateral hydronephrosis was demonstrated ultrasonographically. This patient responded to treatment with a temporary ureteric stent.

Histopathological examination of the resection specimens showed no significant differences between the two groups for length of resected bowel, length of resection margins and number of lymph nodes (*Table 4*).

Discussion

Initial reports of laparoscopic bowel surgery[3–12] suggest advantages but have not included comparative data. In the present study patients for laparoscopically assisted surgery were selected, but a higher proportion had metastatic disease than those treated conventionally, favouring the latter group. The results demonstrate enhanced recovery after laparoscopic surgery.

Pain after laparoscopic operation decreased slightly in the first 24 h and was significantly reduced overall, which should allow more rapid return to normal activity. Return to work at 7 days has been reported[3]. The time to return of bowel function (passage of flatus) was similar in both groups but diet was tolerated earlier by patients undergoing laparoscopic surgery. There were no differences in length of hospital stay but this could have been affected by the less advanced stage of disease in patients treated conventionally. The social circumstances of some of our patients dictate a longer stay in hospital after major surgery than in Europe and North America; two-thirds of patients were transferred to a convalescent ward, which prolonged their stay. Hospital stay of 5–8 days after laparoscopic bowel surgery has been reported[3,4,6].

The abdominal incision was considerably reduced in size for laparoscopic compared with conventional surgery and when full mobilization of the tumour and its mesentery was achieved the use of a grid-iron muscle-splitting incision was possible. It should be possible to achieve a macroscopically clear margin of normal tissue, accepting the limitation that the tumour must be mobile[4]. Loss of touch sensation might allow a surgeon carrying out laparoscopy to cut through a tissue plane containing tumour. Lateral resection margins must be examined histologically with great care but there were no significant differences in the standard histological parameters for the two groups of patients. High ligation of the inferior mesenteric artery can be achieved during laparoscopic surgery, particularly if conventional ligatures are used rather than a stapling device. By dividing the distal resection line through the small abdominal incision an adequate margin can be assured by palpation. Contact between tumour and the sides of the incision must be prevented when it is removed, to avoid implantation[12,13].

Laparoscopic bowel resection is technically more demanding than cholecystectomy and there is concern about providing suitable training[14]. Safety is paramount and a small incision must be extended if necessary. Adding a simple procedure such as tubal ligation to diagnostic laparoscopy results in a doubling of the complication rate[15]. One patient in the present series suffered iatrogenic small bowel perforation, a contributing factor being instruments out of the field of view used for retraction. This complication presented on the fifth day after operation, a time at which anastomotic leakage can present or when patients may be fit for discharge. The shortest reported mean stay after elective laparoscopic bowel resection[3] is 3·8 days and life-threatening complications could occur at home. Patient counselling and communication with community medical services are required.

Careful histological assessment and long-term follow-up are needed for the oncological aspects to be more accurately determined. Laparoscopically assisted anterior resection and sigmoid colectomy are technically feasible, adequate tumour resection can be achieved and recovery after operation is enhanced.

Level D, Royal Surrey County Hospital, Guildford GU2 5XX, UK

A general practice-based programme was initiated in 1987 to identify individuals at high risk of developing large bowel cancer and offer them screening of faecal occult blood. In all, 5298 people from 21 general practices in the Guildford area were offered 7510 screening tests. In total, 5934 tests were completed (compliance rate 79·0 per cent) with 287 positive results (4·8 per cent). Of the patients with positive results, 44 had cancer and 38 polyps. The sensitivity of the test for cancer was 63 per cent, the specificity 96 per cent and the positive predictive value for all neoplasia 29 per cent. The detection rate of 44 cancers per 5934 people screened compares favourably with data from the Nottingham-based screening of an unselected population (0·74 versus *0·23 per cent).*

Recent population screening studies for large bowel cancer in Europe and elsewhere have used a guaiac test for occult blood in the stools (Haemoccult; Rohm Pharma, Weiterstadt, Germany). The positive rates for Haemoccult have varied from 1·0 to 3·7 per cent, with positive predictive values for neoplasia ranging from 32 to 59 per cent and compliance rates from 53 to 74 per cent depending on the method of invitation[1–4].

Patients and methods

In 1987, two general practices matched for population size were approached by a consultant surgeon to set up a targeted screening programme. A flexible protocol was designed to be used by either a doctor or practice nurse in the course of a normal consultation at a health screening clinic or new patient clinic.

A high-risk patient was defined as one over 40 years of age with either bowel or abdominal symptoms or with a family history of one or more first-degree relatives with cancer of the bowel, breast, endometrium, liver, ovary or stomach. Patients with an obvious cause of rectal bleeding, such as untreated haemorrhoids or ulcerative colitis, were not excluded as it was felt that these diagnoses could conceal bleeding from a carcinoma. Family history may identify individuals from 'cancer families' as defined by Lynch *et al.*[5].

Two questionnaires were devised to identify and recruit high-risk individuals into the screening programme; both were given to any patient over 40 years attending the surgery for whatever reason. One was an invitation to general health screening; the other was limited to large bowel screening. A poster was designed for display in the general practice waiting rooms. Credit card style reminders and desk-top reminders containing the protocol and inclusion criteria were also produced. A kit for testing faecal occult blood (FOB) was given to each patient, with written directions for its use. Patients were invited to telephone the surgery for results. Completed kits were returned to the surgery and collected weekly, with record cards. The kits were developed at the hospital and results posted back to the surgery.

Patients with a positive FOB test result were referred for colonoscopy or, in a few instances, fibreoptic sigmoidoscopy plus double-contrast barium enema. Patients' referral letters were identified with a specially designed screening programme stamp to facilitate the earliest possible appointment date for colonoscopy (usually within 1 month).

Individuals with a relevant family history were eligible for recall after 1 year and thereafter every 4 years. Those with a past history of cancer or adenoma were also recalled. Patients with symptoms and no relevant family history were investigated by the general practitioner (GP) or referred to the consultant. Those whose symptoms resolved were discharged from the study. Demographic data and results were entered on a computer database from which patients due for recall were selected at monthly intervals.

Results

In all, 5298 individuals were offered 7510 FOB screening tests; 5934 tests were completed, an overall compliance rate of 79·0 per cent. *Table 1* shows results for the three groups of patients: those with symptoms who had only one test and those with a family history (first and recall results). The compliance rate to recall, which was by postal invitation, was 53·0 per cent, comparable to the 55 per cent obtained by Hardcastle *et al.*[1].

Colonoscopy results for the 287 patients with a positive FOB

Left-sided	3	9	4	
Rectal	2	5	5	
Other (stomach, carcinomatosis)				3
No operation (patient refused)				1

test are shown in *Table 2*. The sensitivity of the test for cancer was 63 per cent, the specificity 96 per cent and the positive predictive value for all neoplasia 29 per cent. The detection rate of 44 cancers per 5934 tests was 0·74 per cent. Twenty-two of the 38 individuals with polyps and nine of the 44 with cancer were asymptomatic with a family history of carcinoma.

Table 3 shows the site and stage of the 44 screen-detected cancers. The patient with an unclassified right-sided tumour did not undergo resection because of extensive local spread. Among patients with symptoms there were five Dukes' A tumours, 15 Dukes' B and 11 Dukes' C. In those with a family history there were three Dukes' A tumours, four Dukes' B and one Dukes' C.

Of the 38 polyps detected, 17 were between 1 and 3 cm in size and 21 less than 1 cm. Twenty-one polyps were tubular adenomas, seven tubulovillous adenomas, one a villous adenoma and nine metaplastic. All the metaplastic polyps were less than 1 cm in size.

Interval cancers occurred in 25 patients and 21 of these had a tumour diagnosed within 1 year of a negative FOB test result. Of the 25 patients, 24 were symptomatic at the time of the test. The asymptomatic patient had a strong family history of bowel cancer and was recalled after 1 year but did not wish to repeat the test. She developed carcinoma of the rectum 3 years after her first test. Only one GP felt that a negative test result had delayed referral of a symptomatic patient.

Discussion

The present compliance rate of 79 per cent does not take account of all individuals potentially at risk. Some people would not have read the questionnaire or failed to respond.

Patient compliance may determine the success or failure of a screening programme. The aim of this programme was to maximize compliance by presenting large bowel screening as part of health screening and preventive medicine. The approach to the patient was through the GP or practice nurse rather than by an impersonal letter. A reduced compliance rate between first and recall testing, and between medical and postal invitation, has been documented in previous studies[6].

The overall positive FOB result rate of 4·8 per cent was high for such a programme as four previous controlled trials of Haemoccult have shown positive rates ranging from 1·0 to 3·7 per cent[1–4]. Since the screening occurred in a high-risk group this result may not be unexpected.

Only eight of the 44 cancers were Dukes' A tumours, which demonstrates the prevalence of the condition in the population and the late onset of symptoms. Two of these tumours were found in polyps which were completely excised by polypectomy. Both patients were asymptomatic with a family history.

Only nine cancers were found in patients with a family history, but 43 per cent of polyps in this group were adenomas over 1 cm in size and therefore at risk of carcinoma[7]. The cancer detection rate was lower in individuals with a family history than in those with symptoms, both overall (0·3 *versus* 1·4 per cent) and in the positive group (8 *versus* 21 per cent). This may justify the inclusion of individuals with symptoms and those with a family history in the high-risk group.

There were 25 patients with interval cancers, but in only one was referral delayed by a negative result. This high proportion highlights the shortcomings of FOB testing. All such tests will miss cancers that do not bleed or bleed only occasionally. Studies of immunological tests such as Fecatwin[8] (Labsystems, Helsinki, Finland) and Hemeselect[9] (SmithKline Diagnostics, San Jose, California, USA) have underlined the importance of the balance between sensitivity and specificity. The sensitivity of Haemoccult is adjusted to maintain a low false-positive rate, but in the present study 36 per cent of cancers were missed. In a high-risk group, it may be more appropriate to use a more sensitive test.

The overall cancer detection rate of 0·74 per cent of patients screened was higher than the 0·23 per cent reported from the randomized controlled trial of unselected individuals in Nottingham[1]. The Nottingham figure was similar to that for the present asymptomatic family history group (0·3 per cent).

The sensitivity of the test for carcinoma was only 63 per cent and there were a large number of interval cancers. Disappointingly few Dukes' A tumours were detected, which may reflect both the low sensitivity of the test and the prevalence of advanced disease in the population.

A group of individuals at increased risk of developing large bowel cancer can be identified through a general practice-based screening programme. Compliance is good and the detection rate of cancers is higher than that found from unselected population screening trials.

Long-term survival after endoscopic transanal resection of rectal tumours

A. J. Dickinson, A. P. Savage, N. J. McC. Mortensen and M. G. W. Kettlewell

Department of Surgery, John Radcliffe Hospital, Oxford OX3 9DU, UK

Correspondence to:
Mr M. G. W. Kettlewell

The outcome and survival of 120 consecutive patients of median age 78 years with rectal tumours who underwent endoscopic transanal resection were assessed. Thirty-eight patients (32 per cent) were treated for large villous adenoma. These patients underwent a median of 2 (range 1–5) resections and the overall 5-year survival rate was 78·2 per cent. Of 82 patients with rectal cancer, 33 (28 per cent of the 120) had tumours amenable to conventional surgery but for the patient's age or infirmity. The 5-year survival rate of these patients was 29·7 per cent. Endoscopic transanal resection was used to palliate the symptoms of 49 patients (41 per cent) with rectal cancer; the 5-year survival rate was 13·7 per cent. Excellent long-term outcome may be achieved with endoscopic transanal resection for patients with benign rectal tumours. This approach also gives acceptable results for selected patients with rectal cancer in whom age, extent of disease or concurrent illness preclude conventional surgical resection.

Curative treatment for patients with rectal carcinoma usually involves *en bloc* excision of the tumour, the mesorectum and its lymphatics to the origin of the inferior mesenteric artery, either as anterior resection or abdominoperineal excision of the rectum[1]. Occasionally, small early rectal tumours are curable by disc excision *per anum*, albeit with a high risk of local recurrence[2]. Elderly patients and, in particular, those with serious comorbidity tolerate major operations poorly[3] and radical surgery is seldom appropriate for those in whom the tumour has progressed beyond cure because of local fixation or distant metastasis. Local excision may also provide worthwhile treatment for patients with large benign rectal tumours.

Endoscopic transanal resection using a urological resectoscope was first proposed in 1979 as a method for palliation of obstructive carcinoma of the rectum[4]. This technique allows resection of extensive rectal adenomas[5–7] and some patients may be cured of rectal cancer by such an approach[8].

Endoscopic transanal resection is a considerably less invasive approach for the treatment of low rectal tumours than conventional surgery and has the benefits of a short postoperative stay, quick recovery, little pain and economy. The technique provides good short-term symptomatic relief[9], but long-term survival data are required before the procedure should be adopted for patients with villous adenoma and localized cancer. The long-term survival of patients undergoing endoscopic transanal resection for benign and malignant low rectal tumours is analysed in this report.

Patients and methods

A retrospective study of patients undergoing endoscopic transanal resection between January 1982 and September 1991 was performed from the operation registers, clinical records and hospital patient administration computer system. Follow-up information was obtained from hospital case notes, general practitioners' records and the Registrar of Deaths.

Operative technique

Bowel preparation comprised a single phosphate enema and, occasionally, two sachets of Picolax (Ferring Pharmaceuticals, Malmö, Sweden). Antibiotic prophylaxis was provided by intravenous cefuroxime 1·5 g and metronidazole 500 mg. Resection was performed using a 36-Fr modified urological resectoscope with continuous glycine solution irrigation as previously described[9].

Patients

Patients were divided into three groups. Group 1 comprised those with histologically proven villous adenoma. In group 2, patients with adenocarcinoma of the rectum in whom clinical assessment and staging suggested that the tumour was amenable to conventional curative resection either refused, or were judged clinically unfit for, major surgery because of age, senility or concurrent disease (American Society of Anesthesiologists grade III or IV). Endoscopic transanal resection was performed with a view to removing all cancer. This approach was considered potentially curative, with the constraints that the tumours were not accurately staged, and that none of the draining lymphatics and little mesorectal fat had been removed. In these patients control of local disease but failure to cure was an acceptable outcome. Five patients with invasive carcinoma in a villous adenoma were included in this group. Group 3 included patients with locally extensive and fixed adenocarcinoma of the rectum, those with distant metastases or those with local recurrence after previous open surgery who were no longer amenable to open excision. In this group endoscopic resection was performed only for palliation.

Statistical analysis

Survival data were analysed by Kaplan–Meier life-table methods[10]. The log rank test was used to determine differences between life-table curves[11]. The proportional hazard and its 95 per cent confidence interval were calculated[12]. Statistical significance was assumed for $P<0·05$.

Results

A total of 120 patients of median age 78 (range 43–92) years underwent 232 endoscopic transanal resection procedures. During the same period, 813 patients underwent open resection of colonic or rectal neoplasms. All tumours resected endoscopically were within 22 cm of the anal verge and 89 per cent within 10 cm. The tumour characteristics are given in *Table 1*.

Morbidity and mortality

Six patients died within 30 days of transanal resection; the operative mortality rate was therefore 3 per cent of operations and 5 per cent of patients. One patient in group 1 died from a myocardial infarction. Five patients with rectal cancer died within 30 days of surgery, two in group 2 and three in group 3. Two patients with rectal cancer died following immediate laparotomy for colonic perforation, and two very frail patients with rectal cancer for whom laparotomy was rejected died from peritonitis after intraperitoneal perforation during transanal

resection. A further patient with rectal cancer died from bronchopneumonia.

There were 38 complications in 23 patients, a morbidity rate of 19 per cent (*Table 2*). Of 17 patients with postoperative haemorrhage, 12 required transfusion or rectal packing. One patient with an intraperitoneal perforation recovered after immediate laparotomy and closure of the perforation. Perforation of the rectum below the peritoneal reflection occurred in most resections for cancer, but only seven patients developed pelvic sepsis as a result. All responded to treatment with antibiotics. Rectovaginal fistulas resulting from tumour invasion and necrosis in all patients developed late in treatment and were often premorbid. Five patients developed stricture following endoscopic resection but were all easily managed by further radial resection of the scar.

Group 1

A total of 38 patients of median age 73 (range 44–86) years underwent 62 transanal resections (range 1–5 per patient); a single resection only was necessary for 28 patients (*Figure 1*). All patients were cured of symptoms by endoscopic resection.

The overall 5-year survival rate for patients with villous adenoma was 78·2 per cent (*Figure 2*) and the disease-specific survival rate 89·2 per cent. One patient aged 86 years died after operation and two (aged 83 and 84 years) died from unrelated conditions. One patient aged 83 years at presentation developed malignant change in a recurrence of villous adenoma and died 41 months after the first transanal resection.

Groups 2 and 3

Some 82 patients underwent 170 transanal resections for rectal cancer; half required more than one procedure (*Figure 1*). Symptomatic relief was achieved for 74 per cent of patients with rectal cancer (*Table 3*). Seven patients subsequently underwent formation of a left iliac fossa colostomy for disabling incontinence. Five patients showed invasive carcinoma on histological assessment of 'chips' of resected villous adenoma removed during transanal resection. One of these patients underwent anterior resection and another abdominoperineal resection.

The 5-year survival rate for all patients with rectal cancer was 20·2 per cent. For patients in group 2, who were treated with transanal resection with intent to cure, the median survival time was 47 months and the 5-year survival rate 29·7 per cent. For patients in group 3, who underwent palliative resection for rectal cancer, the median survival time was 8 months and the 5-year survival rate 13·7 per cent (*Figure 2*).

The 5-year cancer-specific survival rate for all patients with rectal cancer treated with transanal resection was 32·8 per cent. For patients in group 2, the 5-year cancer-specific survival rate

was 48·2 per cent, with a median survival time of 55 months. The cancer-specific 5-year survival rate in group 3 was 21·9 per cent, with a median survival time of 12 months.

Discussion

Patients with rectal villous adenoma present two principal problems: recurrent or residual disease and malignant change. Local or peranal methods of treatment have high recurrence rates of between 10 and 30 per cent[13,14] compared with major resectional surgery. Local excision *per anum*[13] or transanal endoscopic excision[15] are excellent techniques for smaller low lesions. They are more difficult in patients with large, higher villous adenomas and in those with recurrence because the plane of dissection is obliterated at the first operation. Endoscopic transanal resection is a simple treatment, however, and easy to repeat. Most patients in the present series were successfully treated with two procedures. The operative mortality and complication rates compare favourably with those of major surgical resection for patients in this age group.

The incidence of invasive carcinoma in villous adenoma was 12 per cent in this series and 17 per cent in a previous report[13]. Two of these five patients underwent major abdominal resection. The patient who developed invasive adenocarcinoma in a recurrence after transanal resection for villous adenoma illustrates the need for careful histological examination of the resected 'chips'.

Anterior resection and abdominoperineal excision of the rectum for palliation are best avoided if symptoms can be relieved by less traumatic procedures because the operative mortality rate is 21–38 per cent[3,16], recovery slow after major surgery and functional results often poor. The present data confirm a previous report that most symptoms can be controlled by transanal resection[9] and the need for a colostomy delayed or avoided. The survival rate for patients undergoing palliative treatment for rectal cancer was unusually high, with two patients surviving to 5 years after endoscopic resection.

Electrocoagulation is a more time-consuming method of treatment associated with incidences of 22 and 2·5 per cent for postoperative bleeding and perforation respectively[17].

Laser destruction of advanced rectal cancer may be performed as an outpatient procedure and tumours above the peritoneal reflection can be treated. An improvement in 68 per cent of 85 patients treated by neodymium yttrium–aluminium–garnet laser therapy has been reported[18]. In a study by Bright *et al.*[19], however, laser treatment was associated with a 1-month mortality rate of 21 per cent and only 12·5 per cent of patients survived more than 6 months.

Radiotherapy may relieve symptoms in 60–80 per cent of patients with advanced disease[20,21] but may cause rectovaginal fistula, chronic radiation necrosis and stenosis[20].

Advanced age alone is not a contraindication to curative major surgery for rectal cancer with operative mortality rates as low as 4·6 per cent[22] for patients over the age of 70 years and 7 per cent[3] for those over 80 years. The burden of such surgery and the risks of death and complication increase substantially when advanced age is combined with serious comorbidity. An alternative acceptable outcome may therefore be control of local disease without cure.

With the exception of T_1 and T_2 tumours, endoscopic transanal resection seldom removes all rectal cancer. Resection is constrained because little mesorectal fat and none of the draining lymphatics are removed. Tumours cannot be staged accurately for comparative purposes. Endorectal ultrasonography may help to overcome this problem[23,24]. It is difficult to assess the completeness of resection on histological examination. Notwithstanding these limitations, the overall 5-year survival rate of nearly 30 per cent in the present series, and the cancer-specific 5-year survival rate of 48 per cent, are remarkably similar to the 5-year survival rate after open resection of colonic and rectal cancers in the same hospital of 43 per cent[25] and the results of conventional rectal resection reported by some (36 per cent[26] and 44 per cent[27]) but greatly inferior to the 78 per cent from a selected personal series[28]. The unexpectedly good results from an oncologically inadequate operation may arise from selection bias, or repeated thermal injury may inhibit tumour spread. Local surgery may reduce the risks of widespread tumour implantation from open operation and avoids the immunological effects of major surgery and blood transfusion.

This study shows that endoscopic transanal resection is a worthwhile repeatable technique for the treatment of selected patients with rectal cancer and is also a useful alternative to transanal local excision for the treatment of large villous adenoma.

D-dimer: a useful marker of disease stage in surgery for colorectal cancer

C. M. Edwards, J. Warren*, L. Armstrong* and P. K. Donnelly

*Departments of Surgery and *Haematology, University of Leicester, Leicester, UK*

Correspondence to: Mr P. K. Donnelly, Department of Surgery, Leicester General Hospital, Gwendolen Road, Leicester LE5 4PW, UK

It is widely accepted that malignancy is associated with an increased risk of thromboembolic disease[1], and it has been postulated that anticoagulant treatment may improve prognosis after surgery for colorectal cancer[2]. Tumours have a systemic effect on haemostasis that has been likened to a subclinical state of disseminated intravascular coagulation (DIC). The D-dimer assay is a new test specific for degradation products of a stable fibrin clot, and it has proved to be a sensitive marker of DIC[3]. The aim of the present study was to compare the D-dimer assay with conventional coagulation tests, including antithrombin III activity, for investigation of asymptomatic hypercoagulability in relation to tumour stage and response to surgical trauma.

Patients and methods

The study population comprised 12 patients (six men, six women; mean age 73·1 (range 67–88) years) admitted for curative resection of colorectal carcinoma. The control group was 12 patients (five men, seven women; mean age 67·3 (range 47–83) years) undergoing elective open cholecystectomy. All patients received subcutaneous heparin prophylaxis until mobile.

Venous blood samples were collected into 9:1 (v/v) 3·6 per cent sodium citrate 24 h before and 1, 3, 5, 14 and 42 days after operation. Plasma samples were prepared within 2 h of venepuncture and aliquots stored at −20°C. Antithrombin III activity was determined using Immunochrom reagents (Immuno, Dunton Green, UK) on a LabSystem Coagulometer (LabSystems Group, Basingstoke, UK). D-dimer levels were determined by enzyme-linked immunosorbent assay using AGEN Dimertest Stripwell kits (Porton Cambridge, Newmarket, UK). The normal D-dimer level was determined to be 30–160 ng/ml; the maximum value was given by adding two standard deviations to the normal mean. The thrombin time, prothrombin time and activated partial thromboplastin time (APTT) were measured for each patient. Statistical analysis was performed using the Mann–Whitney *U* test and Fisher's exact test.

Results

Histological examination of resection specimens showed no Dukes' A tumours, five Dukes' B (four moderately, one poorly differentiated) and seven Dukes' C lesions (three moderately, four poorly differentiated).

There was no evidence of thrombosis or bleeding in either group of patients, and all had normal thrombin time, prothrombin time and APTT both before and after operation. Antithrombin III activity was not significantly different between patient groups, and it was not affected by tumour stage. Preoperative D-dimer levels were higher ($P < 0.002$) in patients with cancer. Patients with moderately differentiated Dukes' B

tumours had low levels of D-dimer, while those with Dukes' C lesions had high levels ($P<0{\cdot}001$). All patients with Dukes' C tumours but only one with a Dukes' B lesion had D-dimer levels above 160 ng/ml ($P=0{\cdot}006$).

Patients with Dukes' B tumours and those undergoing cholecystectomy showed a similar response to operative trauma (*Table 1*). Patients with Dukes' C tumours had a persistently raised D-dimer level after operation, although by day 42 there was a reduction in D-dimer level compared with the high preoperative value ($P<0{\cdot}001$).

Discussion

The D-dimer assay has demonstrated the existence of subclinical hypercoagulability in the absence of changes in other established coagulation parameters. It has been postulated that tumour-derived procoagulant proteases account for tumour-related coagulopathy, and that they facilitate metastasis by forming fibrin strands around circulating tumour cells, enabling aggregates of cells to lodge in the microcirculation[4]. The present study demonstrates a relationship between advanced human colorectal cancer and increased preoperative coagulation activity as measured by D-dimer production. The fall in D-dimer level observed 42 days after resection of Dukes' C lesions may further indicate a direct relationship between tumour burden and haemostatic disturbance, as has previously been demonstrated[5]. D-dimer is potentially useful as a preoperative marker for advanced colorectal cancer and as such may provide a means of selecting patients who could benefit from adjuvant anticoagulant therapy[2].

Ultrasonographic screening for abdominal aortic aneurysm in an urban community

F. C. T. Smith, G. M. Grimshaw, I. S. Paterson, C. P. Shearman and J. D. Hamer

Department of Vascular Surgery, Queen Elizabeth Hospital, Birmingham B15 2TH, UK

Correspondence to:
Mr F. C. T. Smith

As part of the Birmingham Community Aneurysm Screening Project, 3500 men aged 65–75 years from 20 urban general practices were invited for aortic ultrasonographic screening at their own general practitioner's surgery; 2669 (76·3 per cent) attended. Compliance rates varied between catchment areas, from 52·1 per cent for inner-city areas to 89·6 per cent for suburbs. Successful aortic imaging was achieved in 97·3 per cent of scans. Aortic diameter >29 mm occurred in 219 patients (8·4 per cent) and 79 (3·0 per cent) with a diameter >40 mm were referred for vascular surgical assessment; 140 patients with an aortic diameter of 29–40 mm are currently undergoing follow-up by serial ultrasonographic examinations at intervals of 3 months at their doctor's surgery. Risk factor analysis revealed ischaemic heart disease in 21·9 per cent of men with aneurysm, compared with 11·6 per cent in those without ($P < 0{\cdot}001$)*; 18·3 per cent of men with aneurysm had had a previous myocardial infarction and 13·2 per cent had peripheral vascular disease, compared with 7·4 per cent* ($P < 0{\cdot}001$) *and 8·0 per cent* ($P < 0{\cdot}01$) *respectively of those without. No association was found between aneurysm and hypertension or diabetes. Community-based aortic screening is an inexpensive, effective method of diagnosis of aneurysm, with high compliance from the at-risk cohort of an urban population. Such screening programmes may help to reduce the mortality rate from aortic aneurysm rupture.*

The case for ultrasonographic screening to detect asymptomatic abdominal aortic aneurysm (AAA) is strong[1,2], but remains to be proven. Survival prospects following ruptured aneurysm are poor: more than 50 per cent of patients with rupture die before reaching hospital and even for those who arrive at hospital alive operative mortality rates remain high[3–9]. Conversely, the reported mortality rate for elective surgery is 5 per cent or less[4,6,10,11]; following successful aneurysm repair, life expectancy is restored approximately to that of the normal age- and sex-matched population[3,10,11].

Death from rupture of a previously asymptomatic AAA occurs with increasing frequency in men aged >60 years[1,2,12,13]. Furthermore, epidemiological evidence[14] suggests a linear increase in the reported mortality rate from rupture in England and Wales during the past 30 years. While the disease has its greatest impact in men aged 70–74 years, cost-effective screening is likely to be achieved by ultrasonographic examination of the aorta in the 65–74 years age group of men who are young enough to obtain maximum benefit from elective surgical repair[1]. To date, no controlled trial has established that aortic screening can reduce the mortality rate from ruptured AAA in the community, but important elements of any potentially effective screening programme are a high compliance rate from the population at greatest risk of rupture and an accurate method of screening.

In 1989, the Birmingham Community Aneurysm Screening Project was established. The primary aim was to determine the prevalence of ultrasonographically detected AAA and associated risk factors in an unselected group of men aged 65–75 years within the Birmingham metropolitan area. Other objectives included assessment of the feasibility, accuracy and acceptability of aneurysm screening within the primary-care sector of an urban community.

Patients and methods

Twenty-two general practices representing a cross-section of general practitioners (GPs) in Birmingham were invited to participate in the study. Twenty of the 22 practices approached (77 GPs) accepted. Practice size varied from two partners (4000 registered patients) to nine partners (16 000 patients). All men aged 65–75 years on the age–sex register of participating practices were sent a single postal invitation by their GP to attend screening for AAA at the practice surgery. The style of invitation was dictated by individual practices, based on a suggested pro forma that included a brief explanation of AAA, the method of screening and the existence of effective treatment. Where appropriate, translations into other languages, such as Urdu, were included. Non-responders were not followed up.

Ultrasonographic screening was carried out by a single trained sonographer at GPs' surgeries. Each patient was questioned regarding current medication and smoking habit. A specific history of diabetes, ischaemic heart disease (defined as angina requiring treatment with coronary vasodilators), myocardial infarction (with documented electrocardiographic or enzymic changes), peripheral vascular disease (claudication, transient ischaemic attacks or stroke) and chronic obstructive airway disease (requiring regular treatment with antibiotics or bronchodilators) was also obtained. Blood pressure was recorded. In 364 cases, screening was included as part of a 'well person' health check.

Abdominal aortic scans were carried out using a Pie Data 150S portable ultrasonographic scanner with a 3·5-MHz transducer (Pie Data, Maastricht, The Netherlands). Longitudinal and transverse images of the aorta were obtained from the level of the sternum inferiorly to the aortic bifurcation. Longitudinal scans were used to assess aortic morphology and tortuosity. The maximum anteroposterior or transverse diameter was measured from transverse sections taken at right angles to the aorta at each level. No attempt was made to obtain the suprarenal:infrarenal ratio as the suprarenal aorta could not be visualized reliably on all scans.

Presented to the Vascular Surgical Society of Great Britain and Ireland in Dublin, Ireland, November 1991 and published in abstract form as Br J Surg *1992;* **79***: 358*

0007-1323/93/111406–04 © 1993 Butterworth–Heinemann Ltd

The upper limit of normal aortic diameter was defined as 29 mm. This value was derived from a pilot group of the first 550 men aged 65–75 years in the study, in whom a right-handed skew distribution of aortic sizes occurred. The mode of this distribution was 21 mm. Some 17 per cent of patients had aortic diameters >2 s.d. above the mode and 29 mm (3 s.d.) was therefore taken as a better cut-off point for definition of abnormality.

The accuracy of ultrasonographic measurement was established by blinded reproducibility tests[15] and comparison with computed tomography (CT) findings in 24 patients with aortic diameter >39 mm. The mean difference between CT and ultrasonographic measurements was 0·1 mm, showing no bias between methods. The standard deviation of the differences between methods was 1·78 mm, with a standard error on the distribution of differences of 0·37 mm.

When an abnormal aorta was detected the GP was informed and became responsible for subsequent management. All patients with aortic diameter 29–40 mm were offered follow-up by serial ultrasonography at intervals of 3 months at their GP's surgery. Patients with aortic diameter >40 mm were referred for vascular surgical assessment and follow-up. Elective aneurysm repair was routinely offered only to patients with aneurysm diameter >50 mm, unless surgery was contraindicated (for example, because of severe ischaemic heart disease confirmed by preoperative cardiac assessment and measurement of ventricular ejection fraction). Factors taken into account in the repair of AAAs <50 mm in diameter in four cases were the wishes of the patient, a rapid rate of expansion, or symptoms attributable to the aneurysm.

Analysis of risk factors associated with previously undiagnosed AAA was undertaken using the χ^2 test. $P < 0{\cdot}05$ was considered significant.

Results

Of 3500 men sent invitations, 2669 (76·3 per cent) attended for aortic screening. There was marked variation in compliance between catchment areas, rates ranging from 89·6 per cent attendance (2021 of 2256 invited patients) for suburban practices to 52·1 per cent (648 of 1244) for inner-city areas.

Successful imaging of the infrarenal aorta was achieved in 2597 (97·3 per cent) of initial ultrasonographic scans. In the remaining 2·7 per cent the aorta was obscured by obesity or bowel gas. The mean examination time per patient was 7 (range 5–12) min; a cost per scan of £5·35 was calculated on the basis of salary for screening personnel, travel to general practices, maintenance of ultrasonographic equipment and purchase of consumables.

The distribution of aortic diameter in the screened population is shown in *Figure 1*. A diameter >29 mm was found in 219 of 2597 (8·4 per cent) successfully screened patients. A diameter of 29–40 mm was seen in 140 patients (5·4 per cent); they are undergoing serial ultrasonographic examination at 3-month intervals to monitor aneurysm growth. Increases in aortic diameter have been recorded in 46 (32·9 per cent) of these 140 patients during a mean follow-up of 13 months (mean increase 5 (range 2–18) mm). Seventy-nine patients (3·0 per cent) with aortic diameter >40 mm were referred for vascular surgical follow-up. Only two of these had symptoms attributable to the AAA. Up to 3 years after diagnosis, 56 patients have now undergone aneurysm repair, with one postoperative death (from myocardial infarction) within 30 days of surgery (yielding a hospital mortality rate of 2 per cent). No aneurysm detected by screening has ruptured before planned admission for surgery.

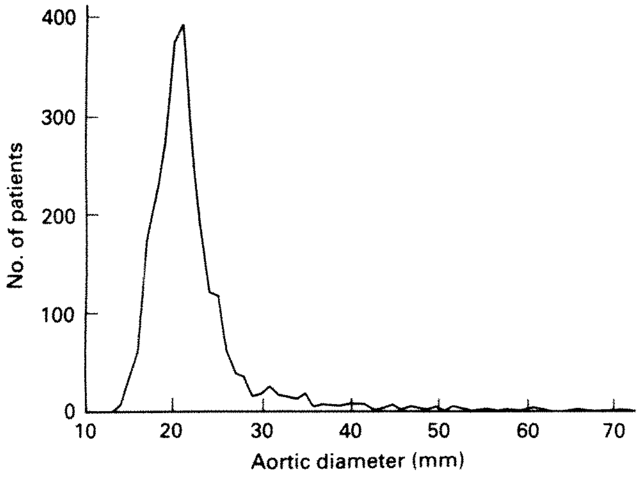

Figure 1 *Distribution of ultrasonographically determined aortic diameter in 2597 men aged 65–75 years*

Table 1 *Prevalence of associated conditions in 2597 successfully screened men aged 65–75 years with aortic aneurysm or a normal aorta*

Associated condition	Aortic aneurysm ($n=219$)	Normal aorta ($n=2378$)	χ^2	P
Ischaemic heart disease	48 (21·9)	277 (11·6)	19·32	<0·001
Myocardial infarction	40 (18·3)	176 (7·4)	31·04	<0·001
Peripheral vascular disease	29 (13·2)	190 (8·0)	7·16	<0·01
Chronic obstructive airway disease	28 (12·8)	205 (8·6)	4·36	<0·05
Diabetes	11 (5·0)	143 (6·0)	0·35	>0·5
Hypertension	42 (19·2)	382 (16·1)	1·47	>0·1
Smoking >10 cigarettes per day	67 (30·6)	418 (17·6)	22·37	<0·001

Values in parentheses are percentages

Table 1 summarizes the prevalence of associated medical conditions in successfully screened patients with AAA or a normal aorta. Of the total screened population, 2612 men (97·9 per cent) had smoked at some time. However, heavy smoking (more than ten cigarettes per day) within 5 years of the time of interview was reported by a significantly greater proportion of men with AAA than by those with a normal aorta.

Discussion

To be effective, a screening programme requires high compliance from the population at risk. An overall attendance rate of 76·3 per cent in the present study compares favourably with results from other screening programmes[16–19], in which the compliance rate ranged from 51·7 to 76 per cent. The high attendance rate can probably be attributed to the invitation to screening being issued by a family doctor known to the patient and to the siting of screening sessions in the close and familiar surroundings of the GP's surgery[17]. Improvement in compliance achieved by GP-based screening has been noted in screening for other diseases[20,21]. A marked difference in the compliance rate between practices located in the inner-city areas (low attendance) and those in suburban areas of Birmingham (high attendance) was observed. This phenomenon has also been reported in breast cancer screening programmes, in which non-attenders tended to be of lower socioeconomic status, were non-partakers of other healthcare services and regarded screening as unnecessary[22]. A further contributory factor to the apparently low rate of compliance in inner-city areas may have been difficulty in maintaining accurate GP patient registers of a transient and relatively mobile population.

In a previous study in the same region, Allen *et al.*[23] found that GPs and hospital doctors who were non-vascular specialists overestimated the risks accompanying aneurysm repair in elderly patients. In this programme, an unforeseen effect of taking screening into the GP's surgery has been an increase, not only in the number of patient referrals for elective aneurysm repair, but also in the audited volume of referrals (27·3 per cent) for other vascular problems.

Accuracy of ultrasonographic measurement is important in screening for AAA, as overestimation of aortic diameter may result in unnecessary anxiety for affected patients and underestimation can leave aneurysms undetected, or lead to lack of appropriate follow-up. Accurate measurement is also necessary for provision of growth data, particularly for small aneurysms for which the potential proportional error of measurement is greatest. The high accuracy of ultrasonographic measurement of aortic diameter compared with values derived from CT in hospital has previously been reported[15]. Specificity of the method was high, with no false-positive diagnoses. It was not possible to assess sensitivity, as men who were apparently normal at first scan have not yet been rescanned. In the present study, all measurements were made by an experienced sonographer using a single ultrasonographic machine. However, accuracy and reproducibility might be adversely affected by employing multiple observers or a variety of types of ultrasonographic equipment in an expanded screening programme[24].

Direct comparison of the prevalence of AAA in the present study with those of other screening programmes is frustrated by important differences in screened groups. In this study, of men aged 65–75 years in a large industrial city, the incidence of aortic diameter >29 mm and >40 mm was higher than that reported from other programmes. In a comparable GP-based study of men of the same age group in a rural area, O'Kelly and Heather[17] found a lower incidence (1·5 per cent) of aneurysm >40 mm, 7·8 per cent of patients having an aortic diameter >25 mm. Collin *et al.*[16], in a hospital-based screening programme targeting men aged 65–74 years in Oxford, using the criterion of a maximal infrarenal aortic diameter at least 0·5 cm greater than the suprarenal diameter or >40 mm, found aneurysms in 5·3 per cent but lesions >40 mm in diameter in only 2·3 per cent. In another recently reported study, Scott and co-workers[18] scanned men and women aged 65–80 years invited by their GPs to attend hospital for screening. Aortic diameter >29 mm was found in 4·3 per cent of the total screened population, but in 8 per cent of men. However, only 2·6 per cent of men had an aneurysm >40 mm in diameter. A higher incidence of aneurysm change of 10·7 per cent was reported in a Swedish population-based study[19] of 364 men aged 74 years who underwent successful ultrasonography in the community of Malmö. Of these, 12 (3·3 per cent) had a maximal aortic diameter >40 mm. The higher incidence in the Swedish study probably reflects the older age of this group of men; 75 years was the upper age limit for screening in the present study.

Not surprisingly, the reported prevalence of AAA is greater in screening studies restricted to high-risk groups: patients with peripheral vascular disease[25,26], hypertension[23,27] and/or coronary artery disease[28,29], and siblings of those with aneurysm[30]. While restricting screening to these groups alone may yield higher AAA detection rates, the overall benefits are likely to be limited as some of these patients will have a poor outlook because of coexisting disease, and many other aneurysms will go undetected.

In common with other reports, patients with aneurysm in the present study had a significantly higher incidence of peripheral vascular disease[16], ischaemic heart disease[19,31], previous myocardial infarction[31] and chronic obstructive airway disease[19,32]. Heavy smokers were also at greater risk of AAA[16,17,19,33]. However, in contrast to some analyses in which hypertension has been reported as a risk factor[23,27], no significant association was demonstrated in the present study; this finding is in accord with those of other population-based screening programmes[16,18,19].

The issue of when to operate on small (4–5 cm) asymptomatic AAAs remains controversial. Some authors advocate serial ultrasonographic follow-up as the risk of rupture of small aneurysms appears to be low[34,35]. Others argue for early elective repair, with low mortality rates, while the patient is relatively young and fit[36,37]. Further prospective data on the growth and outcome of aneurysms <5 cm in diameter are needed. Properly controlled trials of early surgery *versus* serial observation are also essential if the question of when to operate on small aneurysms is to be adequately resolved[38,39].

GP-based ultrasonographic screening of patients aged 65–75 years in Birmingham has revealed an unexpectedly high incidence of asymptomatic AAA. Screening in this way has been well received by patients and GPs alike. It is an inexpensive, effective method of diagnosis with an overall high rate of compliance from this age group of men in an urban population. The incidence of AAA appears to be increasing[14] and broader-based regional or national screening programmes might well contribute to a reduction in unnecessary death from ruptured aneurysm within the community[40].

Abnormalities of the p53 gene and protein were examined in 81 primary breast carcinoma samples. Using a polymerase chain reaction–single-strand conformational polymorphism (PCR–SSCP) analysis, mutations in p53 exons 5–8 were identified in 13 of 81 tumours (16 per cent) and confirmed by DNA sequencing. Positive staining for p53 protein was detected in ten of 77 (13 per cent) of these tumours using polyclonal CM1 antibody on formalin-fixed tissue. Mutations detected by PCR–SSCP analysis were more common in grade III tumours (P=0·015), but no correlation was found with tumour size, node status or level of epidermal growth factor receptor expression. A p53 mutation was associated with positive antibody staining in only two patients. Positive immunohistochemical staining using a p53 antibody may detect p53 protein expression, but this may not correlate directly with an underlying mutation in the hot spot region examined.

The p53 gene, discovered[1,2] in 1979, encodes a 53-kDa nuclear phosphoprotein with a short half-life and has been mapped[3] to the short arm of chromosome 17. The role of normal or wild-type p53 remains obscure, but the protein may be involved in providing a break to cell cycling at the G1–S phase. Mutation of the p53 gene is the most common genetic lesion identified in human carcinoma, including that of the breast, lung and colon[4–6]. Most mutations characterized so far are missense changes that occur within exons 5–8 in a highly conserved mutation 'hot spot' region.

Many p53 mutations alter the conformation of the protein, resulting in abnormal overexpression[4,5]. In normal cells p53 has a short half-life and such a low steady-state level that it is not detectable histologically[7]. By contrast, mutant proteins have an extended half-life[8] and can be detected by histochemical analysis using antibodies specific to p53. Immunohistochemical methods are relatively simple, can be performed in most hospital laboratories and permit screening of many tissue samples. They are, however, often restricted to fresh-frozen material. Recently developed antibodies that detect p53 protein in formalin-fixed paraffin-embedded sections may replace DNA analysis of tumour tissue if the antibodies are shown to detect mutations.

Previous studies of the role of p53 in human breast cancer have examined p53 protein expression[9], chromosome 17p allele loss[10,11] and p53 antibody staining[4,9]. The present study investigated the correlation between p53 mutations detected at the DNA level and p53 protein expression determined by immunohistochemical methods.

Patients and methods

Fresh breast tumour tissue was obtained from 81 consecutive patients undergoing mastectomy or wide local excision for primary breast carcinoma. The specimen was taken on ice to the pathology department and adjacent tumour sections were obtained for haematoxylin and eosin staining, DNA and immunohistochemical analysis, and determination of epidermal growth factor (EGF) receptor level. Tumour was snap-frozen in liquid nitrogen and stored at −70°C pending DNA analysis.

Polymerase chain reaction–single-strand conformational polymorphism analysis

DNA was extracted from fresh-frozen tissue using caesium trifluoroacetate density-gradient centrifugation and purified as described previously[12]. Exons 5–8 of the p53 gene were amplified using the following oligonucleotide pairs:

CCTGCCCTCAACAAGATGTT/CCTCACAACCTCCGTCATGT
ACATGACGGAGGTTGTGAGG/TCATAGGGCACCACCACACT
GGCTCTGACTGTACCACCAT/GGAGTCTTCCAGTGTGATGA
ATCTACTGGGACGGAACAGC/GAGAGGAGCTGGTGTTGTTG

Polymerase chain reaction was performed in a 25-μl reaction volume containing 100 ng human DNA, 2 mmol/l 2′-deoxynucleotide 5′-triphosphates, 25 μmol/l oligonucleotide primers, 1·5 mmol/l $MgCl_2$ and 0·5 units Taq polymerase for 3 min at 94°C; 30 cycles of 94, 55 and 72°C for 1 min each were performed with precautions to avoid contamination. The polymerase chain reaction–single-strand conformational polymorphism (PCR–SSCP) technique was used to detect mutations in the p53 gene. This recently described method identifies a conformational change in a DNA strand resulting from a single base mutation as a band shift on a non-denaturing polyacrylamide gel[13]. PCR was performed incorporating 0·2 μl [α-^{32}P]2′-deoxycytosine 5′-triphosphate and 1 μl radiolabelled PCR product was denatured in 0·1 per cent sodium dodecyl sulphate–10 mmol/l ethylenediamine tetra-acetic acid at 85°C for 5 min. The sample was electrophoresed on a non-denaturing gel containing 5 per cent acrylamide and 5 per cent glycerol at 18°C, using a water-cooled back plate. A band shift, representing a point mutation, was revealed by autoradiography of the dried gel. A positive control for this analysis was the RG15 adenoma cell line known to have a p53 mutation (CGG to TGG) at codon 282 (kindly supplied by Drs C. Paraskeva and A. Williams, Department of Pathology and Microbiology, University of Bristol Medical School). A negative control, in which DNA was replaced with water, was included in each experiment.

DNA sequencing

Direct PCR sequencing was performed on DNA from three patients that demonstrated band shifts on PCR–SSCP analysis[14]. Oligonucleotide end-labelling was achieved using [γ-^{32}P]adenosine 5′-triphosphate and polynucleotide kinase. End-labelled primer (1 μmol/l) was incorporated with the appropriate 2′,3′-dideoxynucleotide 5′-triphosphate (ddNTP) into four PCR reactions per sample (containing 5 mmol/l ddATP, 5 mmol/l ddCTP, 500 μmol/l ddGTP or 10 mmol/l ddTTP), and the denatured PCR products were separated on a 6 per cent polyacrylamide sequencing gel. The sequence was determined from an autoradiograph of the dried gel.

Immunohistochemistry

Immunohistochemical analysis of formalin-fixed paraffin-embedded tumour sections was performed using the CM1 polyclonal antibody (Novocastria, Newcastle upon Tyne, UK)[15]. The 5-μm deparaffinized sections were incubated with Dulbecco's tissue culture medium containing 15 per cent fetal calf serum for 30 min before overnight incubation with CM1 diluted 1:1500 in Dulbecco's medium containing

0007-1323/93/111410-03 © 1993 Butterworth-Heinemann Ltd

calf serum. A streptavidin–biotin–peroxidase system was used with diaminobenzidine in 0·03 per cent cobalt chloride as chromogen. Haematoxylin was used to counterstain the nuclei. In negative controls antiserum was replaced with buffer; positive controls were breast carcinoma sections that were known to stain strongly positive.

Epidermal growth factor receptor analysis

The level of EGF receptor was determined using a ^{125}I-labelled EGF radioreceptor assay with a cut-off value of 10 fmol per mg protein[16].

Results

Pathology

Tumour was obtained from 81 women of median age 58 (range 33–84) years. The median tumour size was 2·5 (range 0·9–9·0) cm and there were 34 T_1 cancers (42 per cent); 37 per cent of women were node positive.

Histological sections were stained with haematoxylin and eosin, formalin-fixed and embedded in paraffin. Invasive ductal carcinoma was found in 58 patients (72 per cent), lobular carcinoma in eight and undifferentiated carcinoma in four. Ductal carcinoma *in situ* was the main diagnosis in four but was present in 36 tumours overall. Seven patients had miscellaneous tumours. Sixteen tumours (22 per cent) were grade I, 28 (38 per cent) grade II and 29 (40 per cent) grade III[17]. Overall, 55 per cent of tumours were positive for EGF receptor and 41 per cent positive for oestrogen receptor.

Polymerase chain reaction–single-strand conformational polymorphism analysis

Band shifts signifying mutations were detected by autoradiography in 13 of 81 tumours (16 per cent). Mutations were identified in exon 5 in five patients, exon 6 in two, exon 7 in four and exon 8 in two. The mutation was verified and precisely located in two samples by direct DNA sequencing; point mutations were identified in codons 243 (ATG to TTG) and 237 (ATG to ATA). DNA from one patient had a large rearrangement at codon 256; there was a 28 base pair repeat inserted after an A to G mutation.

Mutations detected by PCR–SSCP analysis were more common in grade III tumours ($\chi^2 = 8{\cdot}31$, 2 d.f., $P = 0{\cdot}015$) (*Table 1*). No correlation was found between mutations detected by PCR–SSCP analysis and either tumour size, node status or EGF receptor level.

Immunohistochemistry

Formalin-fixed paraffin-embedded tumour sections for immunohistochemical analysis were available from 77 patients. Sections stained using the p53 antibody were examined independently by two observers with an intraobserver and interobserver variation of less than 5 per cent. Samples were scored with respect to the percentage of staining nuclei in cancer cells. A specimen was regarded as positive if more than 1 per cent of the nuclei stained black.

Positive staining was found in ten of the 77 tumours (13 per cent), but in only two of these patients was a mutation detected by PCR–SSCP analysis. No correlation between the two methods was demonstrated.

Table 1 *Correlation between mutations detected by polymerase chain reaction–single-strand conformational polymorphism analysis and tumour grade*

Tumour grade	Mutation in p53 gene	
	Present	Absent
I	0	16
II	3	25
III	9	20

$\chi^2 = 8{\cdot}31$, 2 d.f., $P = 0{\cdot}015$

Discussion

Abnormalities of p53 have been reported in a variety of common adult tumours including breast and colonic carcinoma, osteosarcoma, lung cancer, ovarian carcinoma and leukaemia[18–22]. The availability of p53 antibodies and relative simplicity of the immunohistochemical method have allowed screening of large numbers of tumour samples, particularly since the introduction of the CM1 antibody, which can be used on paraffin-embedded fixed archival tissue. The advantages of immunohistochemistry over PCR-based techniques are considerable: PCR–SSCP analysis is expensive, time consuming, needs to be strictly controlled to avoid contamination and is not routinely performed in most hospital laboratories. However, the relationship between the two methods and the relevance of positive p53 antibody staining must be determined.

Certain p53 mutations are known to result in a protein with an abnormally long half-life, which may be the result of post-translational stabilization or protein binding. This phenotype is present in about 15 per cent of breast tumours but occurs at a much higher rate in lung and colonic cancer[23]. The CM1 antibodies provide a sensitive method for detection of p53 and up to 50 per cent of breast tumours show positive staining[15]. However, only 13 per cent of tumours in the present immunohistochemical analysis showed positive CM1 staining; this may reflect a reduced sensitivity of the technique when formalin-fixed material is used. Excellent results are obtained with CM1 when tissue is fixed in methacarn, formal saline or phenol–formaldehyde, but several factors reduce the intensity of the p53 reaction. Prolonged fixation periods (over 48 h) in formal saline and the presence of calcium in the fixative are both harmful. The temperature should be kept to a minimum during the fixation–processing procedure, although embedding in wax at 60°C cannot be avoided. The precise conditions of fixation of the archival material used in the present study cannot be guaranteed, but processing may have reduced the accuracy of the immunohistochemistry.

No correlation was found between antibody staining and detection of p53 mutations by DNA analysis. The same discrepancy has recently been noted by others[24,25]. Several explanations may account for the difference in the detection of p53 abnormalities. The antibody method detects p53 protein which has an abnormally long half-life. In tumours that have p53 mutations identified by DNA analysis but no p53 detected immunohistochemically, the mutation may produce a stop signal or a large rearrangement or deletion that prevents expression of the protein. Equally, the mutation may produce a protein with a very short half-life that cannot be detected immunohistochemically. Lack of staining may reflect deletion of both p53 alleles. Tumours that stain positively with the CM1 antibody may have no detectable DNA mutation because homogenized tumour tissue is used for DNA analysis; the normal p53 signal from stromal cells may be amplified and sequenced preferentially and thus obscure the presence of a mutation. The mutation may be present within one of the exons, outside the hot spot region, that was not examined in the present study. Mutations within introns may affect RNA splice sites and produce an abnormal p53 protein, or a mutation in an upstream transcription regulator outside the p53 gene could signal excess synthesis of a normal protein. Immunostaining using CM1 may detect p53 protein expression, but this might not be a direct consequence of, or representative of, an underlying mutation in the p53 gene. Stabilization may result from abnormalities of the p53 breakdown pathway, which would also result in higher p53 concentrations.

In this study, p53 abnormalities detected by PCR–SSCP analysis were associated with high-grade breast tumours. It has been shown that p53 mutations arise relatively late in neoplastic progression and may correlate with increasing dysplasia, malignant transformation or increased tumour aggressiveness. This finding suggests that a p53 mutation should be a useful prognostic marker for later stages of breast carcinoma if techniques for DNA analysis become routinely available.

Immunohistochemical detection of p53, a relatively inexpensive and easily controlled method that can be performed in most clinical laboratories, remains a valuable investigation. Detection of stabilized p53 protein may be more important than identifying a mutation if stabilization is responsible for loss of tumour suppressor ability. Examination of the remaining exons of the p53 gene might clarify these results, and further studies that encompass DNA analysis and immunohistochemistry would be valuable.

Resting energy expenditure (REE) was studied in five patients undergoing transhiatal and in 14 undergoing transthoracic oesophagectomy for carcinoma. All resections were performed with an intention to cure. REE was measured by indirect calorimetry before operation and on days 1, 3, 5 and 7 after surgery. Following transthoracic oesophagectomy, REE increased significantly on days 1, 3, 5 and 7 after operation, and on day 7 the value was significantly higher ($P < 0{\cdot}05$) *than that obtained after transhiatal surgery. Energy expenditure following transhiatal oesophagectomy is lower than that after transthoracic oesophagectomy; this may be a result of reduced surgical stress.*

The primary therapeutic goal in patients with oesophageal carcinoma is prompt and effective palliation[1,2]. Surgical resection and reconstruction are associated with appreciable morbidity and mortality rates. Transhiatal oesophagectomy, without thoracotomy, has been advocated to decrease operative morbidity[3]. Controversy exists regarding the relative safety of transhiatal oesophagectomy without thoracotomy and whether this is an appropriate 'cancer operation' compared with transthoracic oesophagectomy with lymph node dissection in patients with carcinoma of the thoracic oesophagus[3,4]. Transhiatal oesophagectomy is associated with higher morbidity and mortality rates than thoracotomy[5,6]. There may be a difference in the magnitude of surgical stress between the two procedures.

This study examined the difference in surgical insult between these two procedures by measuring the resting energy expenditure (REE) by indirect calorimetry. Because REE increases during acute illness, injury and surgery[7], differences in energy expenditure might reflect the extent of physiological insult in patients undergoing oesophagectomy.

Patients and methods

Patient selection

Nineteen men with carcinoma of the thoracic oesophagus underwent either transhiatal or right thoracotomy with reconstruction. All carcinomas were of squamous cell origin. Patients with diabetes mellitus were excluded. Transhiatal oesophagectomy without thoracotomy was performed in five patients. With a single exception, transhiatal oesophagectomy was chosen in patients with stage 0 or I cancer of the oesophagus, assessed by tumour node metastasis staging[8]. Fourteen patients underwent transthoracic oesophagectomy. Staging of the carcinoma after operation indicated that three patients had stage 0, five had stage I, seven had stage IIA and four had stage IIB disease. In the 14 patients undergoing transthoracic surgery, total removal of the tumour and adjacent lymph nodes was achieved and the surgery was considered curative.

Resting energy expenditure

REE was measured with the patient lying at rest before operation and on days 1, 3, 5 and 7 after surgery. The preoperative measurement was performed in the morning after an overnight fast. Nursing procedures such as physiotherapy were not permitted before the measurements.

A commercially available portable system, the RM300 (Minato Medical Science, Osaka, Japan), was used for REE determinations. This device measures the partial pressures of oxygen and carbon dioxide in expired air using a zirconium oxide oxygen analyser and an infra-red carbon dioxide analyser[9]. Measurements were performed continuously, with averages obtained for at least 10 min, at 2-min intervals.

REE was calculated using the modified van de Weir[10] equation:

$$\text{REE (kJ day}^{-1}) = 16{\cdot}3 \times \dot{V}_{O_2} + 4{\cdot}6 \times \dot{V}_{CO_2}$$

where $\dot{V}_{O_2}$ is oxygen consumption (l day^{-1}) and $\dot{V}_{CO_2}$ carbon dioxide production (l day^{-1}). Basal energy expenditure (BEE) was calculated using the Harris–Benedict[11] method to normalize for age, height and weight.

Surgery

In both operative procedures, end-to-end anastomosis between the cervical oesophagus and gastric tube was performed using a double-layered running suture, and pyloroplasty and feeding jejunostomy were carried out.

Of the five patients undergoing transhiatal surgery, one had oesophagogastric anastomotic leakage and another a wound infection. Of the 14 patients undergoing right thoracotomy, one had disruption of the oesophagogastric anastomosis and two developed wound infection. The leak was small and followed shortly by drainage from the neck incision. No patient developed sepsis or a systemic complication. Both leaks closed without further surgery and these patients were considered suitable for inclusion in the study. There were no operative or hospital deaths.

Statistical analysis

Data are presented as mean(s.e.m.). Analysis of variance (ANOVA) with repeated measures was used for comparison of REE data. ANOVA was followed by Scheffé's F test to detect intergroup differences. The Mann–Whitney U test was used for comparing patient details, length of operation, amount of blood loss and nutritional support. Differences between the incidence of infection, anastomotic leakage and wound infection related to operative procedure were analysed using the χ^2 test. $P < 0{\cdot}05$ was considered significant.

Results

Table 1 gives patient details. There was a significant difference in age between the two groups ($P < 0{\cdot}05$). No differences were found between groups in terms of weight at the time of surgery, weight expressed as a percentage of usual weight or BEE. There was no significant association between the operative procedure and the incidence of infection, anastomotic leakage or wound infection ($P = 0{\cdot}42$). No patient developed sepsis during the study. One patient had an additional carcinoma of the stomach, and colon was used for restoration of intestinal continuity.

The mean(s.e.m.) operating times for transhiatal and transthoracic oesophagectomy were 225(22) and 404(16) min respectively ($P < 0{\cdot}005$). There was no significant difference in the mean(s.e.m.) blood loss between transhiatal and transthoracic

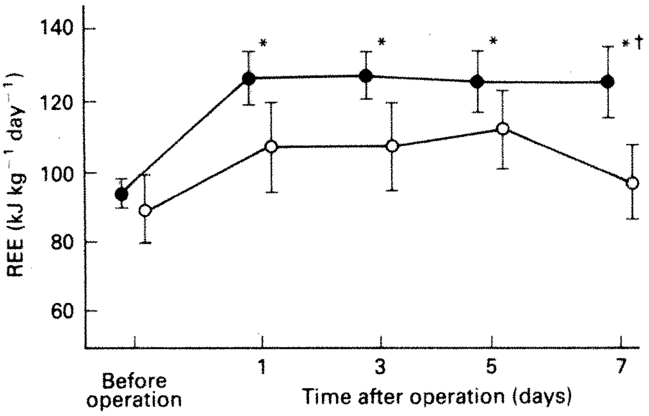

Figure 1 *Changes in the resting energy expenditure (REE) of patients undergoing transhiatal (○) or transthoracic (●) oesophagectomy for carcinoma.* $^*P < 0{\cdot}05$ versus *the preoperative value;* $^\dagger P < 0{\cdot}05$ versus *transhiatal oesophagectomy on day 7 (repeated-measures analysis of variance)*

procedures (467(156) *versus* 748(81) ml). All patients undergoing transthoracic oesophagectomy required mechanical ventilatory support, for a mean(s.e.m.) of 4·1(1·7) days after operation. By contrast, four of the five patients undergoing transhiatal oesophagectomy did not require mechanical ventilation. The patient who required prolonged ventilatory assistance had chronic obstructive pulmonary disease and received support for 30 days.

Postoperative nutritional support is shown in *Table 2*. All patients received total parenteral nutrition in the postoperative period. Feeding via a jejunostomy was begun after the resumption of bowel movement in some patients during the study period.

Changes in the REE of the two groups are shown in *Figure 1*.

Discussion

REE is higher following transthoracic than transhiatal oesophagectomy. Increases in REE have been reported after injury, sepsis and major burns. Patients undergoing major surgery have a rise of up to 24 per cent above the predicted

REE[12]. Because a significant increase in energy expenditure was found after transthoracic oesophagectomy, surgical stress induced by this procedure is likely to be greater than that induced by the transhiatal approach.

Energy expenditure depends on age, nutritional status, energy intake, ambient environmental temperature, and the degree and type of stress[13]. Progressive increase in tumour size is associated with an increase in oxygen consumption[14].

The possibility that the two groups studied were not comparable must be considered. The study was not randomized and there were significant differences in age, tumour stage and patient number between the groups. Transhiatal oesophagectomy was selected for patients in whom the cancer did not invade the surrounding tissues as demonstrated by computed tomography of the mediastinum. Differences in the magnitude of surgical stress between the two groups probably account for the altered REE, for the following reasons.

First, nutritional status and the ambient environmental temperature were identical in the two groups. Second, the difference in REE between the groups before operation was 6·7 kJ kg^{-1} day^{-1}. This is less than the mean difference between groups for REE measured after surgery: day 1, 19·7; day 3, 18·8; day 5, 11·7; and day 7, 31·4 kJ kg^{-1} day^{-1}. Therefore, the observed difference in energy expenditure could not be explained by the age difference between the two groups.

Third, energy expenditure increases following ingestion or intravenous infusion of nutrition as a result of nutrient- or diet-induced thermogenesis[15]. Giovannini *et al.*[16] have shown that 18–25 per cent of REE may come from intravenous administration of nutrients. As the mean difference between the groups in non-protein calorie administration on day 7 after operation was 22·2 kJ kg^{-1} day^{-1}, diet-induced thermogenesis could account for a maximum of 5·4 kJ kg^{-1} day^{-1}. The difference between the groups in REE measured on day 7 after operation was 31·4 kJ kg^{-1} day^{-1}, and it is therefore not plausible that nutrient-induced thermogenesis played a significant role in the observed difference in energy expenditure.

Fourth, the effect of differences in the type of cancer[17] is not relevant because a homogeneous group was studied. The presence of tumour clearly influences host metabolism. Luketich *et al.*[18] reported that REE normalized or remained stable following curative surgery (with no gross evidence of postoperative tumour), while it was hypermetabolic after palliative resection. No patient in the present study had gross evidence of residual tumour after oesophagectomy, making it unlikely that postoperative REE was affected by the presence of tumour.

Finally, transhiatal oesophagectomy took 3 h less to perform and required less blood transfusion than the transthoracic procedure. Postoperative ventilation was required more frequently in patients undergoing transthoracic oesophagectomy. These parameters support the concept that thoracotomy with extended lymphadenectomy is associated with more extensive surgical stress than transhiatal oesophagectomy.

Yamanaka and co-workers[19] have also reported that transhiatal oesophagectomy without thoracotomy involves less physiological insult than radical oesophagectomy with *en bloc* lymph node dissection in the treatment of oesophageal carcinoma.

The REE of patients undergoing transhiatal oesophagectomy is lower than that of those undergoing transthoracic surgery with lymph node dissection. The smaller increase in REE following transhiatal oesophagectomy probably represents reduced surgical stress.

Continuous single-layer serosubmucosal anastomosis in the upper gastrointestinal tract

R. J. C. Steele

Department of Surgery, University of Nottingham, Nottingham, UK
Correspondence to:
Mr R. J. C. Steele, Department of Surgery, University Hospital, Queen's Medical Centre, Nottingham NG7 2UH, UK

In a 4-year period, 100 anastomoses in the upper gastrointestinal tract were fashioned using a single serosubmucosal layer of continuous polydioxanone. One patient required revisional surgery because of anastomotic stricture after partial gastrectomy, but there was no other complication related to the anastomosis. This technique is simple, safe and quick to perform.

The single-layer serosubmucosal anastomosis has a good track record, both in the lower[1] and upper[2] gastrointestinal tracts, but in most series an interrupted technique has been employed. Although Irwin and colleagues[2] used a continuous suture in a proportion of cases, the precise operative technique is not widely known and does not appear to have been described previously. In this paper a method for performing anastomosis in the upper gastrointestinal tract using a single continuous serosubmucosal layer is detailed and a prospective audit of 100 such operations presented.

Patients and methods

Anastomotic technique

The following description is based on a dependent gastrojejunostomy, but the procedure can easily be adapted for the other types of anastomosis listed in *Table 1*. The first step was to make longitudinal enterotomies in both the stomach and jejunum. Major bleeding points were then secured with careful diathermy, but minor bleeding was not a problem because a true appositional serosubmucosal continuous suture is haemostatic. A 3/0 polydioxanone (PDS; Ethicon, Edinburgh, UK) suture on a 25-mm round-bodied needle was then brought through the serosubmucosal layer of the jejunum from a point about 4 mm away from one end of the enterotomy to the cut edge, and then back through the stomach in a similar fashion, leaving the well defined mucosal layers of both organs undisturbed (*Figure 1*). The suture was tied, leaving a 10-cm tail held with an artery forceps, and the needle passed under the knot ready to start the posterior layer of the anastomosis. Suturing proceeded along the posterior aspect of the anastomosis, with needle bites 4 mm deep and 4 mm apart (*Figure 2*). Holding the mucosal layer alone with an atraumatic dissecting forceps helped to define the serosubmucosal layer for accurate placement of the needle.

When the corner had been passed (*Figure 3*), the direction of suturing ideally continued unchanged (*Figure 4*) but, if this was awkward, a single Connell stitch was placed so that a natural forehand movement could be used to complete the anterior layer. After placing the last stitch, the two ends of suture material were simply tied together and the patency of the anastomosis checked by palpation. This technique gave a neat result with no risk of mucosal protrusion, and it could be executed rapidly without compromising precision.

Patients

Over a 4-year period, 100 upper gastrointestinal anastomoses using the continuous serosubmucosal technique were fashioned in 75 patients. All operations were performed by, or carried out under the direct supervision of, a single surgeon. The suture material used was 3/0 polydioxanone in all cases except for four end-to-end pancreatojejunal anastomoses in which 3/0 polypropylene (Prolene; Ethicon) was employed. The types of anastomosis and their indications are detailed in *Table 1*.

In all cases a midline abdominal incision was used and the wound edges were covered by wound towels and a plastic 'ring' wound protector. Perioperative intravenous antibiotic prophylaxis (cefotaxime 1 g) was routinely used and at the end of the procedure the peritoneal cavity was lavaged with 500 ml saline containing tetracycline 500 mg. The fascial incision was closed with no. 1 PDS, and the skin using a variety of techniques.

Table 1 *Details of 100 anastomoses performed in 75 patients*

Operation	No. of anastomoses
Gastrojejunostomy	
For benign pyloric stenosis	5
For inoperable distal gastric malignancy	10
For inoperable pancreatic malignancy	8
After partial gastrectomy for gastric malignancy	21
After antrectomy for bleeding duodenal ulcer	5
After antrectomy as part of biliary diversion	2
After antrectomy as part of Whipple's operation	4
End-to-side jejunostomy (Roux-en-Y)	
After total gastrectomy	12
As part of biliary diversion	4
Side-to-side enteroenterostomy	
Jejunojejunostomy with cholecystojejunostomy	10
Ileoileostomy for bypass of malignant obstruction	3
Ileocolostomy for bypass of malignant obstruction	2
Cholecystojejunostomy	
For bypass of pancreatic malignancy	10
End-to-end pancreatojejunostomy	
As part of Whipple's operation	4

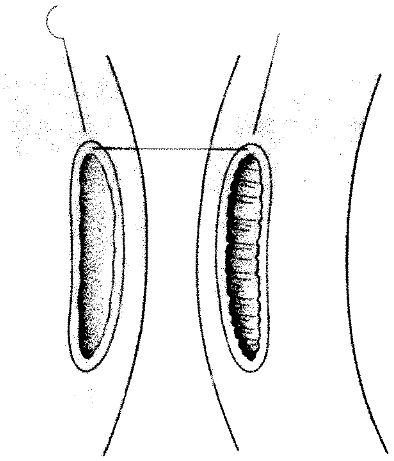

Figure 1 *Start of the anastomosis. The suture is passed through the serosubmucosal layers of the jejunum (on the right) and the stomach (on the left)*

Results

In one patient, who had undergone partial gastrectomy for early gastric carcinoma, anastomotic stricture developed. The stricture required reoperation for persistent vomiting 3 months after the original procedure. There were no wound infections

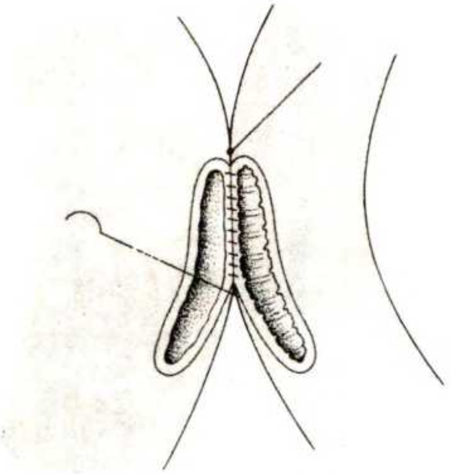

Figure 2 *Suturing of the posterior layer of the anastomosis in progress*

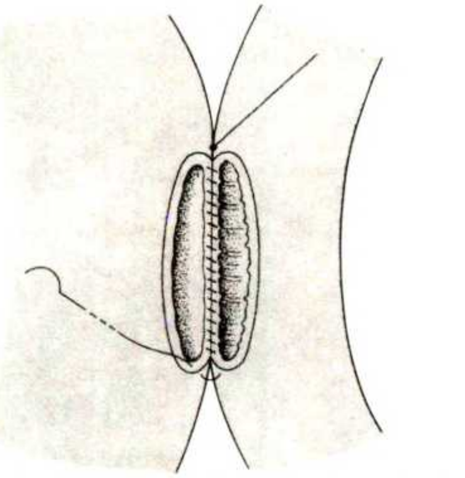

Figure 3 *The posterior layer is complete and the corner is being turned*

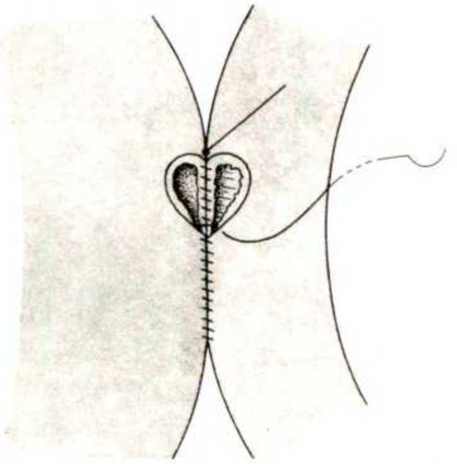

Figure 4 *Suturing of the anterior layer of the anastomosis in progress*

and no other complications related to the anastomosis. One patient died in the immediate postoperative period following gastroenterostomy for inoperable gastric carcinoma. Postmortem examination revealed the cause of death as pulmonary embolism, despite the use of subcutaneous heparin.

Discussion

In an article published in 1887, Halsted[3] was the first to emphasize the importance of the strong submucosal layer of the bowel in anastomotic technique. Based on this observation, Matheson and Irving[4,5] developed the appositional single-layer serosubmucosal method for performing gastrointestinal anastomosis using interrupted sutures[5]. This technique has yielded excellent results and several other authors have confirmed its safety, especially in the large bowel[6-8]. Interrupted sutures have the practical advantage of allowing very accurate matching of bowel ends and the more theoretical advantage of minimizing ischaemia. However, when access is good and the anastomosis technically straightforward, a continuous suture technique is less time consuming, especially when theatre staff are not familiar with the interrupted method.

Single-layer continuous suturing for anastomosis has been described by Sarin and Lightwood[9], who reported leakage rates of 4·5 and 6·2 per cent for the upper and lower gastrointestinal tracts respectively. In their technique all coats of the bowel wall were incorporated in the suture line, but this is neither necessary nor particularly desirable. If only the serosubmucosal layer is employed, the risk of mucosal protrusion is minimized and more precise apposition of the cut edges is feasible.

Fears that a purse-string effect might compromise the lumen have proved unfounded; the single case of anastomotic stricture after partial gastrectomy in the present series was almost certainly caused by failure to create an adequate gastrostomy in the first instance. It might also be argued that the interrupted method causes less disruption to the blood supply and, in demanding situations such as those presented by large bowel or oesophageal resection, continuous suturing is still considered inappropriate. In small bowel, ileocolic and bilioenteric anastomoses, in which mismatching of the cut ends can be a problem, the interrupted technique may also be technically more satisfactory. However, in many situations in the upper gastrointestinal tract, where blood supply and access are not major concerns, continuous single-layer serosubmucosal anastomosis has proved highly satisfactory.

Acknowledgements

The author thanks Mr Z. H. Krukowski for introducing him to the anastomotic technique described in this paper.

Resection-line involvement in gastric cancer: a continuing problem

M. T. Hallissey, A. J. Jewkes, J. A. Dunn*, L. Ward* and J. W. L. Fielding

*Department of Surgical Oncology and *Cancer Research Campaign Trials Unit, Queen Elizabeth Hospital, Birmingham B15 2TH, UK*

Mr M. T. Hallissey

Surgeons are aware of the adverse effect that resection-line disease has on anastomotic leakage, perioperative mortality and long-term survival. In an attempt to assess the effect of this knowledge on surgical practice, patients entered into the second British Stomach Cancer Group adjuvant therapy trial were studied. The presence of resection-line disease was compared with the operative stage. Of 555 patients for whom complete data were available, resection-line disease was present in 105 (19 per cent). Of 424 patients undergoing what the surgeon considered to be a potentially curative operation, 55 (13 per cent) had involvement of one or both resection lines, rendering the surgery palliative. Only 9 per cent of patients with stage I–III disease and resection-line involvement survived beyond 5 years, compared with 27 per cent of those with clear lines. Despite knowledge of the adverse effects of resection-line disease, surgeons continue to perform inadequate resections. This demonstrates the need for a more aggressive approach to assessment of resection margins at operation.

The aim of surgery in the treatment of solid malignancy is to obtain local clearance whenever possible. At present, only 20 per cent of the 10000 cases of gastric cancer diagnosed annually in the UK are suitable for such a radical approach[1]. However, as interest in early detection increases, this proportion is likely to rise[2]. Resection-line involvement has been shown to have an adverse effect on both anastomotic leakage and mortality[3]. The presence of resection-line disease renders a potentially curative operation palliative[4]. As a result, the long-term survival rate is impaired, with a reduction of over 20 per cent[5] at 5 years. While a number of methods have been suggested to achieve adequate clearance[6,7], most surgeons rely on clinical judgement at operation to decide on the extent of resection. This study looked at the value of this approach to determine whether it provides satisfactory results or whether a more aggressive policy of assessment of resection lines would be beneficial.

Patients and methods

Surgeons referring patients to the second British Stomach Cancer Group trial of adjuvant therapy in gastric cancer were asked to record details of the site and extent of tumour, and the surgery they performed, in a manner similar to that recommended by the Japanese Research Society for Gastric Cancer[7]. Information was requested on serosal involvement, lymph node involvement (and to which group the involved nodes belonged), whether there was ascites or metastatic spread, and whether macroscopic clearance had been achieved. This information has been used to provide an operative stage for the patients using the system outlined in *Table 1*, which is based on the protocol staging system.

Pathological data were collected on serosal and resection-line involvement. Pathologists were also asked to record the number and site of nodes examined as well as whether they contained metastases. All initial pathological assessment was undertaken at the referring hospital and a central review of representative blocks performed by Professor D. Levinson (Guy's Hospital, London, UK). The review blocks did not always include resection margins. Therefore, the resection-margin assessment used is that reported by the pathologist from the referring centre. The presence of serosal or nodal involvement and the surgeon's assessment of clearance have been used to provide a simplified pathological stage using the system in *Table 1*. Both operative and simplified pathological stage have been used to look at the incidence of inadequate surgery as assessed by resection-line involvement.

Table 1 *Simplified system for operative and pathological staging*

Stage	Serosal involvement	Lymph node involvement	Macroscopic clearance
I	−	−	+
II	+	−	+
III	±	+	+
IV	±	±	−

Patients were entered into the study if they fulfilled the entry criteria, which have been detailed previously[1]. The basic criteria were that the patient had stage II–IVAi gastric cancer, was under 75 years of age, had survived the perioperative period and was fit to receive adjuvant therapy. In addition to the trial patients, data were also recorded on patients with stage I disease who failed to fulfil one or more of the entry criteria or where only a completed pathology form was available. Where appropriate, patients have been followed in specialist clinics to death or for a minimum of 5 years.

Data were stored on a minicomputer at the Cancer Research Campaign Trials Unit and analysis undertaken using BMDP Statistical Software (BMDP, Los Angeles, California, USA)[8]. This allowed restaging of patients using the simplified system and cross-tabulation between surgical and pathological data. Pearson's χ^2 test was used to detect any associations in the categorical data.

Survival was the primary endpoint of the study. All patients had a minimum follow-up of 5 years. Survival curves were drawn by the method of Kaplan and Meier, and differences between curves assessed using the log rank test. Stratified log rank analysis was undertaken for patients with disease of pathological stage I–III to determine the impact of resection-line involvement on survival in those undergoing otherwise potentially curative resection. The log rank trend statistic was computed to test whether patients with resection-line involvement in stages I–III had significantly adverse survival than those without involvement. Patients with stage IVA disease were included in the analysis as a separate group for comparison.

Results

Complete surgical and pathological data were available for 555 of the 639 patients referred. The remaining patients were excluded because data were missing for one or more of the staging criteria and in six because of missing follow-up data.

Figure 1 *Effect of resection-line involvement on survival in patients with gastric cancer of stage I (——), stage II (– – –) and stage III (----) without resection-line involvement (−), stages I–III with resection-line involvement (+) (–·–) and stage IVA (·····).* $\chi^2_{\text{trend}} = 49{\cdot}23$, *1 d.f.,* $P = 0{\cdot}0001$ *(log rank analysis of stages I–III clear* versus *stages I–III involved resection lines* versus *stage IVA)*

In 18 patients a pathology form alone was received, in 37 the pathologist was unable to identify any nodes in the specimen, in one the depth of penetration was not recorded, in ten no resection-margin assessment was undertaken, and in 19 data were missing for one or more operative assessment criteria. The number of lymph nodes assessed per patient ranged from 1 to 36 (median 5). The number of involved nodes ranged from 1 to 24 (median 1). Using the operative staging system, 65 patients had stage I disease, 108 stage II, 251 stage III and 131 stage IVA. One or both resection margins were involved in 105 patients (19 per cent). The proximal margin alone was involved in 60 patients, the distal margin alone in 27 and both in 18. The relationship between operative stage and resection-line involvement is shown in *Table 2*. Not surprisingly, there is a significant trend for early-stage disease to be associated with a smaller percentage of involved resection margins ($\chi^2_{\text{trend}} = 25{\cdot}48$, 1 d.f., $P < 0{\cdot}0001$).

Using the simplified pathological staging system, a significant linear trend was observed ($\chi^2_{\text{trend}} = 30{\cdot}71$, 1 d.f., $P < 0{\cdot}00001$) in the incidence of resection-line disease by pathological stage (*Table 3*). In 11 per cent of patients without nodal involvement and disease confined to the stomach, the sole site of known residual disease was the resection margin.

The site of resection-line disease in patients undergoing potentially curative surgery varied with the type of operation performed ($\chi^2_{\text{trend}} = 3{\cdot}78$, 1 d.f., $P = 0{\cdot}05$). In those undergoing total gastrectomy, the proximal margin alone was involved in 15 per cent of cases, with both margins being involved in 4 per cent. There was no case of involvement of the distal margin alone. For patients undergoing partial gastric resection, the figures were similar with single-line involvement at around 11 per cent. A full breakdown is given in *Table 4*.

Log rank analysis showed that resection-line involvement had a significant adverse effect on survival ($\chi^2 = 52{\cdot}93$, 1 d.f., $P < 0{\cdot}00001$), with 355 deaths in the 450 patients without involved lines compared with 100 deaths in the 105 with involved lines. Across all stages, survival was significantly impaired in patients with involved resection margins. The details are shown in *Table 5*.

Survival for patients with simplified pathological stage I, II and III disease with and without resection-line involvement is shown in *Figure 1*. The curve for stage IVA is included for comparison. Log rank analysis demonstrated a significant trend for patients with involved lines or stage IVA disease to have a poorer survival ($\chi^2_{\text{trend}} = 49{\cdot}23$, 1 d.f., $P < 0{\cdot}0001$). Survival for those with resection-line involvement was similar to that for patients with macroscopic residual disease; only five patients (9 per cent) with resection-line involvement survived to 5 years.

Discussion

Surgical treatment of solid malignancy aims for complete removal of disease whenever possible. The extent to which this goal is achieved is likely to be influenced by the surgeon's perceptions of the prognosis of the disease. The poor overall prognosis for patients with gastric cancer, only 5 per cent[9] surviving to 5 years, plays a part in the nihilistic approach to treatment adopted by many clinicians. However, this figure hides the fact that many patients never undergo surgery. Of those with disease localized to the stomach, the 5-year survival rate following resection[10] is over 35 per cent, this figure rising to over 90 per cent for those with disease confined to the mucosa and submucosa[11].

Although surgeons are not accurate in their assessment of serosal or lymphatic involvement, they can identify a group of patients in whom macroscopic clearance can be achieved. At present, the proportion of patients suitable for such an approach[9] is about 20 per cent but with the growing interest in early detection this figure should increase[2]. Where macroscopic clearance is possible, appropriate radical surgery is essential to provide the best hope of cure. When disease is left at the margins after gastric resection, both operative mortality and survival have been shown to be impaired. The presence of resection-line disease at the margin of oesophageal resection has been shown[3] to increase the anastomotic leakage rate from 7 to 100 per cent and the fatal leakage rate from 3 to 100 per cent. In addition, long-term survival is known to be impaired[5]. Using log rank analysis the presence of resection-line disease was seen to be associated with a 20 per cent reduction in the 5-year survival rate and regression analysis has confirmed that it is an independent prognostic variable[10]. The impact on long-term survival has been confirmed in the present study, with survival similar to that seen in patients with macroscopic residual disease. Only 9 per cent of patients with stage I–III disease and resection-line involvement survived to 5 years, compared with 27 per cent of those with clear lines.

A number of methods have been suggested to avoid leaving disease at the resection margins. In defining the surgery required for absolutely curative gastrectomy, the Japanese demand a 5-cm margin from the edge of the tumour[7], a distance that has been validated by further work from Japan[12]. Gall and Hermanek[6] have suggested that the margin may be defined on the basis of preoperative assessment of the histological type of the tumour. In those considered to have the intestinal type of lesion, a margin of 4 cm is recommended. For the group considered to have the diffuse type, the margin should be 8 cm, which would require total gastrectomy in the majority of patients with the diffuse type of tumour[6]. A national study from Norway[13] provided some evidence to support this approach. The incidence of proximal resection-line involvement in those with diffuse tumours was 21 per cent compared with 9 per cent for intestinal tumours[13]. However, this approach, while supported by a historical comparison, lacks prospective confirmation[6]. A third method of deciding on the extent of resection is to undertake intraoperative assessment of the margins by either cytological or frozen-section examination[3]. In addition to routine frozen-section assessment, the use of immunocytochemistry with specific monoclonal antibodies to schirrous carcinoma has been reported to increase the sensitivity of the technique[14]. Although it has been shown to be accurate and is generally available, frozen-section assessment of resection margins is not widely used.

The adequacy of resection is usually decided on clinical grounds by the surgeon at operation. The results of the present study have shown that surgeons are not good at determining the extent of resection required to achieve microscopic clearance within the stomach. The presence of resection-line disease is unlikely to have a major impact on survival in those undergoing palliative surgery and the approach to the extent of resection in such cases goes some way to explain the very high level of resection-line disease in this group. However, in patients considered by the surgeon to be undergoing surgery for disease confined to the muscularis, the incidence of resection-line involvement was unacceptable at 11 per cent. Even when the pathology data are considered, 15 (11 per cent) of the 140 patients without evidence of lymph node dissemination had the resection margin as the only known site of residual disease. Overall, resection-line involvement was the sole site of residual disease in 55 (13 per cent) of the 424 patients undergoing otherwise potentially curative surgery, rendering their operations palliative.

The present study, because of the timing of referral, was not able to provide data on the effect of involvement of resection margins on perioperative morbidity and mortality, and it is important to recognize that these figures represent the minimum incidence of resection-line involvement. These are the postoperative survivors, and the literature indicates that perioperative mortality is highest among those with resection-line disease[3]. Among these survivors, the adverse effect of resection-line involvement on long-term survival has been confirmed. The median survival time for patients with pathological stage II disease is reduced by over 50 per cent and for stage III disease the reduction is 37 per cent.

Although the adverse effects of resection-line disease have been known for some time, the present study has demonstrated that surgeons still perform inadequate surgery, not only in patients with extensive disease but also in those in whom they feel they have some hope of providing a surgical cure. These results clearly demonstrate the need for a much more aggressive policy towards intraoperative assessment of resection lines if the best outcome is to be offered to patients undergoing surgery for gastric cancer. As a minimum, frozen-section assessment of the resection margins should be routine in all those undergoing potentially curative surgery.

Vertical banded gastroplasty for the treatment of morbid obesity

S. Ashley, D. L. Bird, G. Sugden and C. M. S. Royston

Department of Surgery, Hull Royal Infirmary, Anlaby Road, Hull HU3 2JZ, UK

Correspondence to:
Mr C. M. S. Royston

Prospective evaluation of 114 obese patients (96 women, 18 men) undergoing vertical banded gastroplasty over a 5-year period was undertaken. The age range was 17–58 (median 37) years, median weight 119·3 (range 79–216) kg, mean(s.d.) proportion of excess body-weight 104·1(34·9) per cent and median body mass index (BMI) 44·8 (range 33·2–77·7) kg/m^2. Three gastric outlet stoma circumferences were used: 5·5 cm (31 patients), 5·0 cm (28) and 4·75 cm (55). A total of 109 patients (95·6 per cent) were available for follow-up. At 1 year after operation, 54 patients (59 per cent) had lost greater than 50 per cent of excess body-weight. No patient lost less than 25 per cent of excess body-weight, and the median BMI was 32·5 (range 21·3–47·8) kg/m^2. The operative mortality rate was zero, but three patients (2·6 per cent) with gastric leakage required surgical revision. Vertical banded gastroplasty is a relatively safe and simple procedure that produces significant and sustained weight reduction in the majority of morbidly obese patients.

Severe obesity is a serious nutritional disorder associated with physical and psychosocial morbidity and mortality. Surveys suggest that 5 per cent of men and 7·5 per cent of women in Western countries are severely obese[1,2]. Morbid obesity is defined as body-weight twice the ideal (according to average weight for height from the actuarial tables of the Metropolitan Life Insurance Company[3]), 45 kg (100 lb) above ideal weight or a body mass index (BMI = weight/height^2) greater than 39 kg/m^2. It is associated with significantly diminished life expectancy[4,5].

Surgical treatment by intestinal bypass[6] was superseded by gastric bypass in the late 1960s. Roux-en-Y gastric bypass has become the standard with which other procedures are compared, although dumping, and iron, folate and vitamin B_{12} deficiencies are not uncommon complications[7].

More recently, various types of gastroplasty have been described. Vertical banded gastroplasty[8] is currently the most frequently performed procedure for morbid obesity in North America and probably worldwide. The attraction of this operation is its technical simplicity and reduced perioperative morbidity rate compared with gastric bypass[7,9,10]. A recent survey, however, showed that bariatric surgery is still practised by only a minority of surgeons in the UK[11].

This study prospectively evaluated the outcome of obese patients undergoing vertical banded gastroplasty in a district general hospital over a 5-year period.

Patients and methods

Since 1986, 114 consecutive patients (96 women, 18 men; median age 37 (range 17–58) years) have undergone vertical banded gastroplasty. All patients were suffering from chronic severe obesity (duration more than 5 years) and had failed conservative efforts to reduce weight.

The ideal weight for height of patients was determined from the midpoint of adult weight range for height tables obtained from the Metropolitan Life Insurance Company[3]. Before operation the median weight was 119·3 (range 79–216) kg, mean(s.d.) proportion of excess body-weight 104·1(34·9) per cent and median BMI 44·8 (range 33·2–77·7) kg/m^2.

Patients were selected for operation after extensive counselling by a team comprising surgeon, nurse clinician, dietitian and clinical psychologist. Twenty-one patients (18·4 per cent) had a BMI less than 39 kg/m^2 at the time of surgery but had all been morbidly obese at some stage previously and had lost some weight by dietary means. A history of alcohol abuse or past psychiatric disorder was considered an absolute contraindication to surgery.

Subcutaneous heparin and broad-spectrum antibiotic prophylaxis were administered routinely.

Operative details

The operative technique has been described in detail elsewhere[8,12]. The median pouch volume was 20 (range 15–50) ml. Initially, the pouch volume was measured during operation using a volumetric filling technique but once consistency had been established the volume was subsequently estimated. The stoma was supported externally by an encircling 1·5-cm wide band of Marlex (C. R. Bard, Billerica, Massachusetts, USA) or GORE-TEX (W. L. Gore, Woking, UK). Three different stoma band circumferences were used: initially 5·5 cm Marlex (31 patients), then 5·0 cm Marlex (28) and, more recently, 4·75 cm GORE-TEX (55). Cholecystectomy was performed in 20 patients (17·5 per cent) in whom coincidental gallstones were found at laparotomy.

Elective postoperative ventilation was undertaken only in patients whose weight was above 189 kg. Patients were usually discharged on day 5 or 6 after operation.

Under the supervision of the dietitian, all patients received mineral and vitamin supplements, a fluid diet for the first 6 weeks and purèed food for the next 6 weeks. A light solid diet was gradually reintroduced thereafter.

Patients were seen at monthly intervals by the dietitian and nurse counsellor to ensure compliance with the dietary regimen. After the initial postoperative visit, medical follow-up was undertaken at 6 months and then annually. Barium or endoscopic examination was performed if indicated.

Statistical methods

Body-weight was expressed as the percentage above ideal weight (percentage of excess weight) for the following time intervals: 6 months, and 1, 2, 3 and 4 years after surgery. The percentage of excess body-weight lost was derived at each time interval.

Patients whose stoma bands were removed because of septic complications were excluded from subsequent weight loss analysis. Those who underwent revisional surgery for weight gain were excluded from analysis after the second procedure. To compare the three different stoma sizes, the mean percentage of excess body-weight lost at each time interval was calculated for each band size and compared using one-way analysis of variance. The incidence of vomiting within each of the stoma size groups was compared using the χ^2 test.

Presented to the Association of Surgeons of Great Britain and Ireland in Oxford, UK, April 1991

Results

Five patients failed to attend any follow-up appointments. Of the 109 patients (95·6 per cent) available for follow-up, three were excluded from subsequent weight loss analysis owing to postoperative complications necessitating stoma band removal. Thirteen further patients failed to attend on certain occasions. Follow-up data were available on 95 patients at 6 months, 91 at 1 year, 47 at 2 years, 19 at 3 years and five at 4 years.

Weight loss was most rapid during the first year after surgery, after which it was maintained in the majority. *Table 1* shows the number of patients who lost up to 25, 50, 75, or 100 per cent or greater of excess body-weight at each time interval, as well as the mean percentage of excess weight lost. All patients lost weight initially; 1 year after surgery the median BMI was 32·5 (range 21·3–47·8) kg/m^2 and only 12 patients (11·3 per cent) had a BMI greater than 39 kg/m^2 (i.e. were morbidly obese). Five patients (4·7 per cent) eventually regained weight owing to disruption of the vertical staple line or pouch dilatation.

The percentage of excess body-weight lost with time for each stoma band size is shown in *Figure 1*. During the first year the trend was for greater weight loss in patients with smaller stomas. This difference was statistically significant at 6 months ($P < 0·05$, one-way analysis of variance) but subsequently there was no significant difference in the mean weight loss between the three stoma sizes. The numbers of patients within each stoma size group available for longer term follow-up were, however, small.

Table 1 *Frequency distribution of percentage of excess weight lost after vertical banded gastroplasty*

	No. of patients at each time after surgery				
	6 months	1 year	2 years	3 years	4 years
Total no. at follow-up	95	91	47	19	5
Percentage of excess weight lost					
0–25	2	0	2	0	3
26–50	54	37	14	10	1
51–75	35	37	25	8	1
76–100	4	16	6	1	0
>100	0	1	0	0	0
Mean(s.d.)	48·4(14·1)	58·3(17·5)	54·5(19·4)	52·4(15·7)	46·4(16·3)

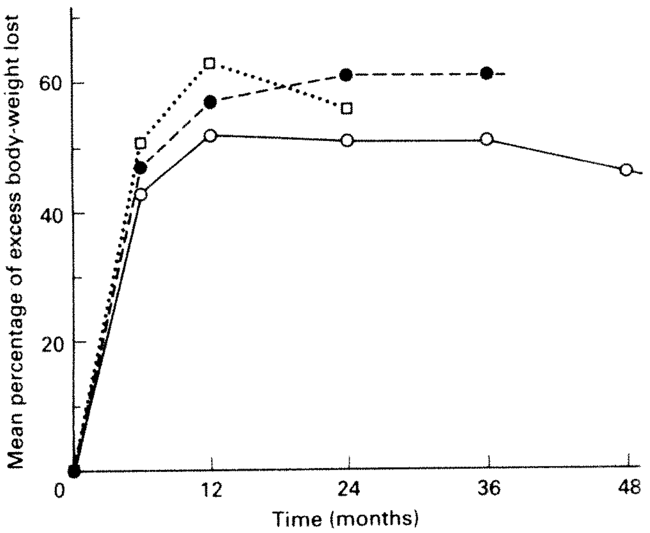

Figure 1 *Mean percentage of excess body-weight lost with time for each gastric stoma band circumference: ○, 5·5 cm; ●, 5·0 cm; □, 4·75 cm. Error bars are omitted for clarity*

Table 2 *Complications following vertical banded gastroplasty*

Complication	No. of patients	Comments
Gastric leakage	3 (2·6)	One patient developed recurrent subphrenic abscesses and a gastric fistula
Respiratory	12 (10·5)	Eight chest infections, three respiratory failures, one respiratory arrest
Wound infection	5 (4·4)	No wound dehiscence
Myocardial infarction	1 (0·9)	
Upper gastrointestinal haemorrhage	1 (0·9)	Severe lower oesophagitis on endoscopy
Vertical staple-line disruption	3 (2·8)*	Regained weight
Pouch dilatation	2 (1·9)*†	Regained weight. Both patients had 5·5-cm bands
Stomal stenosis	10 (9·4)*†	Eight patients had 4·75-cm bands, one had a 5·0-cm and one a 5·5-cm band
Persistent vomiting	2 (1·9)*†	Both patients had 4·75-cm bands but no endoscopic evidence of stomal stenosis. One revised, one lost to follow-up
Bolus obstruction	1 (0·9)*†	Plum-stone retrieved at endoscopy

Values in parentheses are percentages of total number of patients. *Percentage based on number available for follow-up; †percentage excludes those without stoma bands

In addition to maintained weight loss, other less objective parameters of success were documented in many patients, such as employment of those previously without jobs and pregnancy in women who were previously infertile.

Complications

Table 2 shows the incidence of complications. There were no deaths. Because patients with leakage from the gastric staple line required further laparotomy and removal of the stoma band, they were excluded from subsequent weight loss analysis. Of the three patients with disruption of the vertical staple line, two started to regain weight concomitant with the ability to eat normally. One patient reported an ability to eat normally despite satisfactory weight loss. One patient has subsequently declined further follow-up or treatment, another has undergone successful revision by reinsertion of the vertical staple line at laparotomy, and the third is awaiting revision.

Both patients with dilatation of the proximal gastric pouch are awaiting revisional procedures.

One patient with a 5·5-cm band regained weight after 3 years despite initially satisfactory weight loss. This patient declined further investigation, follow-up or treatment and the cause of weight increase is therefore unknown.

The majority of patients with stomal stenosis presented with persistent vomiting between 3 and 16 months after surgery. These patients were treated successfully by endoscopic dilatation. One patient with persistent vomiting despite no evidence of stomal stenosis underwent successful surgical revision by exchange of her 4·75-cm band for one of 5·0 cm. The greater incidence of stomal stenosis and vomiting in the group with 4·75-cm outlets compared with that in the 5·0- and 5·5-cm groups was significant ($\chi^2 = 6·61$, 2 d.f., $P < 0·05$).

Discussion

Weight loss following vertical banded gastroplasty in the present study compares favourably with that reported by others[12–16], although the number of patients reaching longer term follow-up is limited. In patients followed for 5 years or more, Mason *et al.*[17] reported a mean excess weight loss of

58 per cent, suggesting that vertical banded gastroplasty can achieve long-term weight reduction.

In a small proportion of patients failure to lose weight may be due to staple dehiscence or stoma–pouch dilatation[13,18,19]. The principal cause of failure to lose weight is non-compliance with postoperative dietary advice. Careful patient selection and continued emotional support and long-term dietary advice are required.

The relative safety of the procedure is borne out by this and other studies[12–16,18,19]. An operative mortality rate of 0·3 to 0·4 per cent has been reported[20,21]. The most serious complication is gastric leakage, which is fortunately rare, occurring in 0·8 per cent of primary operations[13,21,22]. In the present study there were three gastric leaks (2·6 per cent), with serious consequences in one. This complication may be reduced in incidence or avoided altogether by serosal reinforcement of the circular staple window and covering with omentum, as well as routine testing of the pouch and staple lines by instillation of methylene blue during operation[12].

The optimal pouch volume[12,17,23] is probably 15–30 ml, although there is little in the way of objective evidence to support this. Various methods of measuring pouch volume have been described[23]. Surgeons unfamiliar with the technique of vertical banded gastroplasty should measure volumes until consistency is achieved. Evidence suggests that the stoma of 5·5-cm circumference is associated with significantly less weight loss and more long-term failures, and should no longer be used[12,17]. Very small stoma sizes (under 4·5 cm) may, however, result in inadequate weight loss and a high incidence of vertical staple-line dehiscence[16]. An outlet circumference of 4·75–5·0 cm is probably ideal, although in the present study there was a higher incidence of vomiting in the 4·75-cm group.

All patients with stomal stenosis were successfully managed by endoscopic dilatation. With one exception all patients who required dilatation had Gore-Tex bands, which produce far less tissue reaction and fibrosis than those made from Marlex.

Several studies have compared vertical banded gastroplasty with gastric bypass[7,10,24]. Roux-en-Y gastric bypass is superior to vertical banded gastroplasty in terms of weight loss, but gastric bypass is usually more effective in 'sweet eaters' owing to unpleasant dumping symptoms[10,24]. If patients with a particularly high dietary intake of sweets are excluded, Roux-en-Y bypass results in about 10 per cent more excess weight lost than vertical banded gastroplasty, but at the expense of more postoperative complications[7,10,24]. Others have shown[25,26] that, with close dietary supervision, malnutrition does not occur following vertical banded gastroplasty.

Vertical banded gastroplasty is a safe and relatively simple operation that results in worthwhile and sustained weight reduction in the majority of morbidly obese patients.

Comparative audit: fact *versus* fantasy

G. P. Copeland

Department of Surgery, Warrington District General Hospital, Lovely Lane, Warrington WA5 1QG, UK
Correspondence to: Mr G. P. Copeland

Comparison of the quality of surgical care has often proved to be an enigma. It still remains more in the realms of fantasy than fact. On the other hand, the quantity of surgical care is fairly easy to determine, audit and compare. Waiting and turnover times, numbers of patients seen and operated on, and the financial cost of surgical intervention can all be measured. Many non-surgeons have used such figures to equate with surgical quality, but this should clearly not be done. Quality is a much more difficult determinant to measure, and the outcome of surgical endeavours must be taken into consideration if anomalies are to be avoided. This fact is exemplified by the surgeon with a 100 per cent perioperative mortality rate. Surgery in this case will be cheap, the turnover rate rapid and waiting time short (no follow-up being necessary), but the quality will be non-existent.

How then can one attempt to define quality? Although many complex definitions are possible, the patient and surgeon each has a simple question to ask. The patient will want to know: 'How good is a surgeon or unit?'. The surgeon will ask: 'How am I performing?'. To address these questions, the possible outcomes of a surgical operation must be determined. The most easily identifiable outcomes are death and complication, and it is not surprising that rates of mortality and morbidity are chosen most often as quality measures. These parameters can be approached using a variety of methods.

Mortality and morbidity meetings form the mainstay of methods used to estimate surgical quality and are the basis of audit in both Europe and the USA. While of obvious benefit, there are three basic difficulties in such an approach. The first is a dichotomy inherent to all audit. On the one hand improvement depends on learning from information about performance, but on the other the same information can easily be used to make and enforce judgements that provoke fear and prevent learning[1]. It is this dilemma that produces most anger and fear among surgeons and remains a major obstacle to the advancement of comparative audit. The second problem with mortality and morbidity meetings is that discussion of a particular death or complication often takes place without reference to whether such an outcome could have been expected. Peer review and hindsight are not always good predictors, even after the effect of bias has been excluded. Third, such meetings exclude discussion of the surgical success: the patient in whom death or complication could have been expected but did not occur. Theoretically such cases have as much, if not more, to teach us as those in which a poor outcome could have been expected.

Unit performance can be compared with published rates for mortality and morbidity in similar units. In this regard a lead has been taken by the Confidential Comparative Audit Service of The Royal College of Surgeons of England[2]. This service allows comparison to be made of workload and resources, but quality issues are more difficult to extrapolate. In 147 882 general surgical admissions reported by Dunn and Fowler[3], the mortality rate varied from 0 to 5 per cent (mean 1 per cent) and the morbidity rate from 0 to 23 per cent (mean 6 per cent). Does this imply that the unit with a 5 per cent mortality rate is worse than one with a rate of 0 per cent? Such an approach has certainly been used to compare cardiothoracic units in the USA. Comparison between units in operative mortality rate following coronary artery bypass grafting has been used in some areas[4,5] to assess quality. Reaction to such 'raw' mortality data by the public and some of the medical profession has led to the closure of units and the discontinuation of programmes. The effect that such data could have on litigation has yet to be quantified. It is of no surprise that differences in outcome occur between units; indeed, such variation is to be expected[6]. It is essential, however, if practice variations are to be assessed, that differences in case-mix are considered.

The recent development of quality-assurance guidelines may induce similar problems, unless used with caution. Certainly one danger of large databases is that mortality and morbidity standards could be set that misrepresent the units with the highest and lowest rates. Although such methods may be helpful in highlighting the need for audit enquiry, they are not reliable enough to allow comparative audit. In an attempt to avoid these difficulties, various groups have devised techniques for producing risk-adjusted mortality and morbidity rates. These methods of quality analysis depend on ability to predict outcome. This objective can be achieved in three ways: scoring systems, regression analysis or a combination of both. Using such techniques, risk-adjusted mortality assessments have been devised for cardiothoracic[7] and general[8] surgery. In the general surgical setting, the POSSUM (Physiological and Operative Severity Score for the enUmeration of Mortality and morbidity) system has the added advantage of producing a risk-adjusted assessment for morbidity as well as for mortality.

These techniques compare data from individual units with a concurrent established database to produce a corrected mortality rate[7] or an observed:expected ratio[9]. A ratio of 1·0 indicates that a unit is performing operations to a quality equal to the mean. A rate of less than 1·0 indicates a performance better than that expected and a value greater than 1·0 worse than expected. These ratios have an obvious practical advantage over 'raw' mortality and morbidity data and allow comparative audit to be contemplated. In the general surgical setting even major differences in case-mix can be accounted for using the POSSUM system[9].

The major danger with all comparative audit data is, of course, their potential for misuse. In the USA this potential has been realized with the publication of uncorrected mortality and morbidity rates, and their use for both overt and covert advertising. Similar problems are beginning to appear in the UK[10]. Risk-adjusted outcome measures could potentially avoid some of these abuses. As yet, such an approach has been developed only for cardiac[7,11,12] and general[8] surgery. In the USA, controlling bodies and groups of surgeons use these differences in risk-adjusted mortality rate between units to assess site visits, so as to examine possible variation in systems and processes. Such an approach has two major advantages over existing audit methods. Examination of 'good' units should highlight potentially better surgical technique and practice, which could be of benefit to all. Examination of the poorer performing units may highlight deficiencies known to these that, because of other influences such as financial constraints and staffing levels, they are not able, unaided, to correct. In the latter instance, the full weight of medical audit opinion may produce the necessary improvement. We should not be afraid to find deficiencies in surgeons and to approach these in the same way.

If surgeons are to improve the quality of work, we must be brave enough to assess our own performance and compare it with that of others. If deficiencies are found, we must be both prepared and allowed to examine the systems that surround us

0007-1323/93/111424-02 © 1993 Butterworth-Heinemann Ltd

and the methods adopted. Such analyses will take time and resources, and surgeons need to be more forthcoming with the results of their audit deliberations if this investment is not to be wasted. It is essential in this regard, if improvement is to be attempted, that there is trust and patience between clinicians and managers.

Can comparative audit become more than fantasy? The Royal College of Surgeons has taken a lead at a national level, but with the development of risk-adjusted outcome analysis the methodology exists to examine quality in a more systematic way on a local as well as national scale. Comparative audit can become fact, but we must have the courage to embrace it. It should never be forgotten, as eloquently stated by Berwick[1], that, as well as the auditor's courage, others must show the wisdom of restraint if continuous quality-improvement is to follow from comparative audit.

Reoperation for biliary tract complications following orthotopic liver transplantation

P. Ramirez, P. Parrilla, F. S. Bueno, R. Robles, J. A. Pons* and F. Acosta†

*Departments of General Surgery, *Gastroenterology and †Anaesthesia, Hospital 'Virgen de la Arrixaca', University of Murcia, El Palmar, Murcia, Spain*

Correspondence to:
Dr P. Ramirez

Biliary tract complications were analysed after 54 orthotopic liver transplantations performed in 49 patients over a 2-year period. Reconstruction of the bile duct consisted of end-to-end choledochocholedochostomy over a T *tube in 47 cases and Roux-en-*Y *choledochojejunostomy in seven (two for sclerosing cholangitis, one for secondary biliary cirrhosis, four retransplants). The* T *tube was withdrawn 12–16 weeks after operation in all but two patients (2–3 weeks). There was no intraoperative mortality. Eight patients (16 per cent) died during the first month and the 1-year actuarial survival rate was 75 per cent. Early biliary complications (up to 3 months after operation) consisted of five bilomas, for which ultrasonographically guided drainage was effective in three and surgical drainage necessary in two. Late biliary complications (3 months onwards) consisted of biliary peritonitis following* T *tube removal (four patients; reoperation was required in all four) and necrosis of the bile duct secondary to a late arterial thrombosis (one). The incidence of reoperation as a result of early biliary complications was low (two patients), but higher for biliary peritonitis following* T *tube removal.*

Despite technical improvements in orthotopic liver transplantation (OLT), biliary complications are still a frequent cause of postoperative morbidity[1–5]. The incidence of less than 10 per cent reported recently[2,6] is far removed from the 34–50 per cent noted in 1977 by Starzl *et al.*[7] and Calne and colleagues[8]; most publications[1,4,5,9–12] show an incidence of 10–34 per cent. The aim of the present study was to analyse biliary tract complications after the first 54 liver transplantations performed in this hospital.

Patients and methods

Over a 2·5-year period, a total of 54 OLTs were performed in 49 patients (30 male, 19 female) aged between 10 and 63 years. Indications for transplantation are listed in *Table 1*.

For the first eight grafts, EuroCollins solution was used as a preservation fluid; for the remaining 46, University of Wisconsin solution was employed. The mean(s.d.) cold ischaemia time for the donor liver was 405(104) (range 180–700) min. In 15 cases (28 per cent) haemodynamic intolerance to clamping of the inferior vena cava and portal vein led to the use of venovenous bypass. The mean(s.d.) time for surgery on the recipient was 479(113) (range 280–705) min.

All the liver removals from the donor and implants in the recipient were performed using the technique described by Lerut *et al.*[3] and Calne[13]. Reconstruction of the biliary tract consisted of end-to-end choledochocholedochostomy in 47 cases and Roux-en-Y choledochojejunostomy in seven (two for sclerosing cholangitis, four retransplants, one for secondary biliary cirrhosis). Choledochocholedochal anastomosis was performed with a single layer of interrupted 4/0 resorbable suture (polyglactin); a T tube was left in the bile duct and the long limb brought out through a small incision in the recipient duct, at least 1 cm from the divided end. Choledochojejunal anastomosis was also performed with a single layer of interrupted 4/0 polyglactin, and a multiperforated stenting cannula left in the anastomosis. The stent was pulled through after being fixed to the jejunal loop using Witzel tunnelation. All patients with a choledochocholedochostomy underwent routine intraoperative cholangiography after reconstruction. The T tube and stent were removed after 12–16 weeks, except in one patient whose T tube was accidentally dislodged in the third week (without biliary complications) and in another with a choledochojejunostomy, whose stent was removed early (week 2) after a severe episode of cholangitis; no biliary tract complications were observed in this patient and the cholangitis subsided.

month, two patients died, both from sepsis and multiorgan failure: one infection was intra-abdominal (infected haematoma) and the other of pulmonary origin. Between 3 and 12 months a further two patients died, one from sepsis of pulmonary origin and the other from acute uncontrolled rejection while awaiting retransplantation. Finally, after 1 year, one patient died from pulmonary metastasis after a recurrence of hepatoma. The actuarial survival rate of the 49 patients receiving 54 OLTs was 75 per cent at 12 months and 70 per cent at 28 months (*Figure 1*).

Biliary tract complications

Complications occurred in ten cases (19 per cent) and six needed surgical treatment.

Early biliary tract complications (before the third month) occurred in five cases (9 per cent) (*Table 3*). All presented with a bile collection in the subhepatic space (biloma); one was associated with an external bile fistula around the T tube. Three of the patients had symptoms of cholestasis and high levels of bilirubin and alkaline phosphatase, and two presented with fever with pain and muscle guarding in the right hypochondrium. Ultrasonography in all cases disclosed a collection of subhepatic fluid. Cholangiography revealed a bile leak in three patients. In the other two (those with fever and muscle guarding) there was dislodgement of the T tube from the biliary tract. Ultrasonographically guided drainage was attempted in all five patients and proved effective in three; the two failures occurred in those with sepsis and T tube dislodgement, for whom surgery was indicated. In one patient (on day 20 after operation) the T tube was reinserted and a subhepatic drain was left; in the other (on day 25) the T tube was removed and a subhepatic drain left. Both patients progressed without complication.

Late biliary tract complications (from the third month onwards) occurred in four patients who developed diffuse acute peritonitis after T tube removal between 3 and 4 months after surgery. The tube was latex in two cases and silicone in two. All needed an emergency laparotomy within 24–48 h of withdrawal. Abundant peritoneal bile was found in all four patients. The abdominal cavity was lavaged and a subhepatic drainage tube left, which was removed 3–6 days after operation. All four patients progressed satisfactorily.

A further patient was readmitted to hospital 3 months after transplantation (donor liver of an incompatible blood group in a patient with fulminant hepatitis) for symptoms of pruritus and increased levels of transaminase and alkaline phosphatase, but with a normal bilirubin concentration. Cholangiography revealed considerable cavitation at the hepatic hilum. This was confirmed by a liver isotope study, which revealed a number of cavities in both hepatic lobes. Doppler ultrasonography did not show fluid at the hepatic artery. Retransplantation was indicated and surgery revealed hepatic artery thrombosis, necrosis of the whole donor duct and multiple cavities of various sizes in both hepatic lobes. The retransplanted organ developed primary graft dysfunction and further transplantation was needed, this time with arterial reconstruction using anastomosis between the donor thoracic aorta and the recipient infrarenal abdominal aorta. After this second retransplant, the patient developed sudden fulminant signs of hypovolaemic shock (on day 18 after operation) secondary to rupture of an aortic pseudoaneurysm at the arterial anastomosis, and died.

Discussion

Currently, the most commonly used techniques for biliary tract reconstruction in OLT are end-to-end choledochocholedochostomy as a first-choice procedure[1,3,15] and Roux-en-Y choledochojejunostomy in cases where the recipient duct is pathological or there is a clear difference in size with that of the donor[1–3]. However, some workers routinely use other procedures such as the gallbladder conduit[13] or side-to-side choledochocholedochostomy[4,16]. The authors' procedure of choice is end-to-end choledochocholedochostomy[3] and the second option (in cases of sclerosing cholangitis, secondary biliary cirrhosis, retransplant, size difference between donor and recipient ducts) is Roux-en-Y choledochojejunostomy or hepatojejunostomy.

The most frequent biliary tract complications after transplantation are fistula and biliary obstruction[1–5,17,18]. There were no strictures of the anastomosis in the present series; biloma was the commonest complication. Initially, any biloma was treated conservatively with ultrasonographically guided drainage, as advocated in most series[19–21]. Surgery is indicated in two situations: when radiological drainage has not been effective, and when the amount of bile does not tend to decrease with time.

In the present series, the second most frequent complication was fistula with diffuse acute peritonitis following T tube removal. To prevent this complication, some have advocated leaving the T tube in place for longer periods and using tubes made from non-inert materials. This achieves a greater local inflammatory response[22–24], although less so in patients receiving steroids, and enables the formation of a track with well established walls between the bile duct and the exterior, which should prevent diffuse acute peritonitis following withdrawal of the T tube. In the present patients the T tube was left for a minimum of 12 weeks and, when biliary peritonitis developed following tube removal, the tube was silicone in two cases and latex in the other two. One of the patients accidentally dislodged the T tube during the third week after operation, but developed no biliary tract complications. Good results have recently been reported[25] when treating bile leakage after T tube withdrawal with early transpapillary nasobiliary catheter insertion in the course of duodenoscopy.

It should be noted in the present series that more than half of the biliary complications were directly related to the T tube (two bilomas occurred following tube dislodgement from the bile duct and four cases of bile peritonitis followed removal of the tube). To prevent this type of complication, it has recently been suggested[26] (with good results) that a T tube should not be left after performing the end-to-end choledochocholedochostomy. Further studies will be necessary to confirm the efficacy of this procedure.

Necrosis of the bile duct is an infrequent problem associated with arterial thrombosis[18]. One of the present patients developed this complication. Arterial thrombosis in this case may have been related to a hyperacute rejection episode a few days after transplantation, in which the graft was of an incompatible blood group.

In conclusion, although the rate of biliary tract complications following OLT has diminished in recent years, they still represent a frequent postoperative problem. Excluding the four cases of peritonitis following T tube removal and the necrosis of the bile duct secondary to arterial thrombosis, the incidence of biliary tract complications in the present series was minimal (9 per cent), possibly owing to the experience of the surgical team[27,28].
